# 1. Assessment of the Walleye Pollock Stock in the Gulf of Alaska

Cole C. Monnahan, Grant D. Adams, Bridget E. Ferriss, S. Kalei Shotwell, Denise R. McKelvey, and David W. McGowan

November 2023

# **Executive Summary**

# **Summary of Changes in Assessment Inputs**

### Changes to input data

- 1. Fishery: 2022 total catch was updated and catch at age added. The 2023 TAC was used for catch in 2023.
- 2. Shelikof Strait acoustic survey: 2023 biomass index and age composition.
- 3. NMFS bottom trawl survey: 2023 index and length compositions
- 4. Summer acoustic survey: 2023 index and length compositions
- 5. ADF&G crab/groundfish trawl survey: 2023 biomass index

### Changes in assessment methodology

This year there was no change in model structure, but there was a transition to a new modeling platform named Template Model Builder (TMB; Kristensen *et al.* (2016)). A bridging analysis showed that the former 19.1a ADMB model and TMB model were equivalent, with differences of less than 0.02% in estimates and uncertainty of SSB and recruitment. Given a change in modeling platform, the previous model 19.1a was renamed to 23.0. Moving to TMB allows for more flexibility in modeling process errors due to its ability to efficiently apply the Laplace approximation to get the marginal likelihood in complex, non-linear hierarchical models. We explored a suite of alternative fisheries selectivity models (Appendix 1F) but did not bring them forward for consideration this year. The advantages of this flexibility will be explored in depth in future years, but the focus this year was to transition the assessment to the new platform.

# **Summary of Results**

The base model projection of female spawning biomass in 2024 is 274,141 t, which is 54.3% of unfished spawning biomass (based on average post-1977 recruitment) and above B40% (202,000 t), thereby placing GOA pollock in sub-tier "a" of Tier 3. New surveys in 2023 include the winter Shelikof Strait acoustic survey, summer acoustic survey, summer NMFS bottom trawl survey, and the ADF&G bottom trawl survey. These survey indices showed somewhat divergent trends, with large increases in the summer NMFS bottom trawl (79.4%) and summer acoustic (71.7%) from 2021, but decreases in the winter acoustic (-29.2%) and ADF&G bottom trawl survey (-22.5%) from 2022. Together the new data led to an increased spawning population relative to the prediction from last year.

The risk matrix table recommended by the Scientific and Statistical Committee (SSC) was used to determine whether to recommend an ABC lower than the maximum permissible. The table is applied by evaluating the severity of four types of considerations that could be used to support a scientific recommendation to reduce the ABC from the maximum permissible. We identified some elevated

concerns about the stock assessment, but none for population dynamics, environment/ecosystem, or fisheries performance categories. We therefore recommend no reduction from maximum permissible ABC.

The recommended 2024 ABC for pollock in the Gulf of Alaska west of 140° W lon. (W/C/WYK regions) is 232,543 t, which is an increase of 56.1% from the 2023 ABC. The recommended 2025 ABC is 157,687 t. The OFL in 2024 is 269,916 t, and the OFL in 2025 if the ABC is taken in 2024 is 182,891 t. These calculations are based on a projected 2023 catch of 145,215 t and the ABC for years 2024 and 2025. The estimated scale of the stock increased about 40% compared to previous years, driven by new data, particularly the new high biomass indices from summer surveys.

For pollock in southeast Alaska (Southeast Outside region, east of 140° W lon.), the ABC recommendation for both 2024 and 2025 is 9,749 t (see Appendix 1B) and the OFL recommendation for both 2024 and 2025 is 12,998 t. These recommendations are based on a Tier 5 assessment using the projected biomass in 2024 and 2025 from a random effects model fit to the 1990-2023 bottom trawl survey biomass estimates of the assessment area.

### Status Summary for Gulf of Alaska Pollock in W/C/WYK Areas

\*Projections are based on an estimated catch of 145,215 t for 2023 and estimates of 232,543 t and 157,687 t used in place of maximum permissible ABC for 2024 and 2025.

# Status Summary for Gulf of Alaska Pollock in the Southeast Outside Area

|       |      |          |          |

# **Responses to SSC and Plan Team Comments on Assessments in General**

None this year.

## **Responses to SSC and Plan Team Comments Specific to this Assessment**

The GOA Plan Team in its November 2019 minutes recommended the author examine fishery selectivity, as persistent patterns in the catch-at-age residuals may represent artifacts of the selectivity functional form used.

An extensive analysis of non-parametric and parametric fisheries selectivities was undertaken in 2023 (Appendix 1F). These models showed promise for improving residual patterns, but had some lingering estimation and stability issues that need to be more thoroughly addressed. This will be done next year.

In December 2021 the SSC highlighted the need to examine catchability for the winter Shelikof acoustic survey.

The SSC supports future research to identify the optimal level of constraint on among-year variation in Shelikof Survey catchability (q), including the potential to estimate the process error variance internally within the assessment model.

The SSC reiterates its recommendation from December 2020 to explore the use of covariates related to the timing of the survey to inform survey catchability in the Shelikof Strait survey. For example, the difference in timing between peak spawning and mean survey date or, alternatively, the proportion of mature fish in the survey, are likely to inform time-varying catchability in the survey.

Currently the winter Shelikof acoustic survey catchability is modeled as a random walk with assumed process error. The original logic was that some of the stock spawned outside of Shelikof Strait and thus were unavailable to the survey. Fish tended to spawn in other areas with some consistency, so a random walk on catchability was implemented to account for variation in spatial availability. Several overlapping efforts were done to explore alternative catchability structures. None of these are proposed for 2023, but were presented for Plan Team feedback in September 2022 and remains ongoing collaborative research for this stock. In particular a WHAM version of the GOA pollock assessment was used to explore estimating the constraint (process error), and to quantify the amount by which timing covariates can reduce that, in effect parsing spatial and temporal availability. Preliminary results are very promising but still under scientific review and thus not adopted this year. We anticipate having something formal to present in 2024.

In October 2023 the SSC supported the GOA GPT recommendation that additional examinations are necessary to determine best method(s) for projecting near term trends when time-varying and auto-correlated selectivities are used in assessments.

We examined this in Appendix 1F and found that using model predictions from non-parametric selectivity modules (2D and 3D AR(1)) generally outperformed the status quo of using an average of the most recent 4 years with data. The non-parametric functions led to improved retrospective patterns, but also lower predictive error (RMSE) in a retrospective analysis when predicting a single year out and comparing it to estimates with the data in the subsequent year. Non-parametric modules are not feasible to fit in a robust way in ADMB models, and so the new 23.0 TMB pollock model provides an important research tool to explore issues with time-variation and projections. We anticipate further research along these lines in 2024.

# Introduction

# **Biology and Distribution**

Walleye pollock (*Gadus chalcogrammus*; hereafter referred to as pollock) is a semi-pelagic schooling fish widely distributed in the North Pacific Ocean. Pollock in the central and western Gulf of Alaska (GOA) are managed as a single stock independently of pollock in the Bering Sea and Aleutian Islands. The separation of pollock in Alaskan waters into eastern Bering Sea and Gulf of Alaska stocks is supported by analysis of larval drift patterns from spawning locations (Bailey *et al.* 1997), genetic studies of allozyme frequencies (Grant and Utter 1980), mtDNA variability (Mulligan *et al.* 1992), and microsatellite allele variability (Bailey *et al.* 1997).

# **Stock Structure**

The results of studies of stock structure within the Gulf of Alaska are equivocal. There is evidence from allozyme frequency and mtDNA that spawning populations in the northern part of the Gulf of Alaska (Prince William Sound and Middleton Island) may be genetically distinct from the Shelikof Strait spawning population (Olsen et al. 2002). However, significant variation in allozyme frequency was found between Prince William Sound samples in 1997 and 1998, indicating a lack of stability in genetic structure for this spawning population. Olsen et al. (2002) suggest that inter-annual genetic variation may be due to variable reproductive success, adult philopatry, source-sink population structure, or utilization of the same spawning areas by genetically distinct stocks with different spawning timing. There are important recent preliminary results from a genetic analysis of 617 walleye pollock from Japan, Bering Sea, Chukchi Sea, Aleutian Islands, Alaska Peninsula, and Gulf of Alaska using low-coverage whole genome sequencing. Results suggests there is a temporally stable stock structure with a latitudinal gradient, i.e., Bering Sea pollock are distinguishable from those in the Gulf of Alaska and Aleutian Islands (I. Spies, personal communication, 2021). An evaluation of stock structure for Gulf of Alaska pollock following the template developed by NPFMC stock structure working group was provided as an appendix to the 2012 assessment (Dorn et al. 2012). Available information supported the current approach of assessing and managing pollock in the eastern portion of the Gulf of Alaska (Southeast Outside) separately from pollock in the central and western portions of the Gulf of Alaska (Central/Western/West Yakutat). The main part of this assessment deals only with the C/W/WYK stock, while results for a tier 5 assessment for southeast outside pollock are reported in Appendix 1B.

# Fishery

The commercial fishery for walleye pollock in the Gulf of Alaska started as a foreign fishery in the early 1970s (Megrey 1989). Catches increased rapidly during the late 1970s and early 1980s (Table 1.1; Fig. 1.1). A large spawning aggregation was discovered in Shelikof Strait in 1981, and a fishery developed for which pollock roe was an important product. The domestic fishery for pollock developed rapidly in the Gulf of Alaska with only a short period of joint venture operations in the mid-1980s. The fishery was fully domestic by 1988.

# **Description of the Directed Fishery**

### **Catch Patterns**

The pollock target fishery in the Gulf of Alaska is entirely shore-based with approximately 96% of the catch taken with pelagic trawls. During winter, fishing effort targets pre-spawning aggregations in Shelikof Strait and near the Shumagin Islands (Figs. 1.2 and 1.3). Fishing in summer is less predictable,

but typically occurs in deep-water troughs on the east side of Kodiak Island and along the Alaska Peninsula.

### **Bycatch and Discards**

Incidental catch in the Gulf of Alaska directed pollock fishery is low. For tows classified as pollock targets in the Gulf of Alaska between 2018 and 2022, on average about 95% of the catch by weight of FMP species consisted of pollock (Table 1.2). Nominal pollock targets are defined by the dominance of pollock in the catch, and may include tows where other species were targeted, but pollock were caught instead. The most common managed species in the incidental catch are arrowtooth flounder, Pacific ocean perch, Pacific cod, sablefish, shallow-water flatfish, and flathead sole (Table 1.2). Sablefish incidental catch had trended upwards since 2018, but has fallen in the last 2 years. The most common recent non-target species are squid, miscellaneous fish, smelt, capelin, and grenadier (Table 1.2). Bycatch estimates for prohibited species caught as bycatch in the pollock fishery. A sharp spike in Chinook salmon bycatch in 2010 led the Council to adopt management measures to reduce Chinook salmon bycatch, including a cap of 25,000 Chinook salmon bycatch in the directed pollock fishery. Estimated Chinook salmon bycatch since 2010 has been less than the peak in 2010 and was 13,130 in 2022.

## **Management Measures**

Since 1992, the Gulf of Alaska pollock Total Allowable Catch (TAC) has been apportioned spatially and temporally to reduce potential impacts on Steller sea lions. The details of the apportionment scheme have evolved over time, but the general objective is to allocate the TAC to management areas based on the distribution of surveyed biomass, and to establish three or four seasons between mid-January and fall during which some fraction of the TAC can be taken. The Steller Sea Lion Protection Measures implemented in 2001 established four seasons in the Central and Western GOA beginning January 20, March 10, August 25, and October 1, with 25% of the total TAC allocated to each season. Allocations to management areas 610, 620 and 630 are based on the seasonal biomass distribution as estimated by groundfish surveys. In addition, a harvest control rule was implemented that requires suspension of directed pollock fishing when spawning biomass declines below 20% of the reference unfished level.

Recently NMFS approved the final rule for Amendment 109 to GOA Fishery Management Plan developed by the North Pacific Fisheries Management Council. Amendment 109 combines pollock fishery A and B seasons into a single season (redesignated as the A season), and the C and D seasons into a single season (redesignated as the B season), and changes the annual start date of the redesignated pollock B season from August 25 to September 1. These changes were implemented beginning in 2021 and affect the seasonal allocation only in the Central and Western GOA.

# Data

The data used in the assessment model consist of estimates of annual catch in tons, fishery age compositions, NMFS summer bottom trawl survey estimates of biomass and age and length compositions, acoustic survey estimates of biomass and age composition in Shelikof Strait, summer acoustic survey estimates of biomass and age and length composition, and ADF&G bottom trawl survey estimates of biomass and age composition (Figure 1.4). Binned length composition data are used in the model only when age composition estimates are unavailable. The following table specifies the data that were used in the GOA pollock assessment:

| Source  | Data        | Years     |
|---------|-------------|-----------|
| Fishery | Total catch | 1970-2023 |

| Source                          | Data               | Years                 |
|---------------------------------|--------------------|-----------------------|

## Fishery

### Catch

Total catch estimates were obtained from INPFC and ADF&G publications, and databases maintained at the Alaska Fisheries Science Center and the Alaska Regional Office. Foreign catches for 1963-1970 are reported in Forrester et al. (1978). During this period only Japanese vessels reported catch of pollock in the GOA, though there may have been some catches by Soviet Union vessels. Foreign catches 1971-1976 are reported by Forrester et al. (1983). During this period there are reported pollock catches for Japanese, Soviet Union, Polish, and South Korean vessels in the Gulf of Alaska. Foreign and joint venture catches for 1977-1988 are blend estimates from the NORPAC database maintained by the Alaska Fisheries Science Center. Domestic catches for 1970-1980 are reported in Rigby (1984). Domestic catches for 1981-1990 were obtained from PacFIN (Brad Stenberg, pers. comm. Feb 7, 2014). A discard ratio (discard/retained) of 13.5% was assumed for all domestic catches prior to 1991 based on the 1991-1992 average discard ratio. Estimated catch for 1991-2020 was obtained from the Catch Accounting System database maintained by the Alaska Regional Office. These estimates are derived from shoreside electronic logbooks and observer estimates of at-sea discards (Table 1.4). Catches include the state-managed pollock fishery in Prince William Sound (PWS). Since 1996, the pollock Guideline Harvest Level (GHL) of 2.5% for the PWS fishery has been deducted from the total Acceptable Biological Catch (ABC) by the NPFMC Gulf of Alaska Plan Team for management purposes (see SAFE introduction for further information). Non-commercial catches are reported in Appendix 1E.

### Age and Size Composition

Catch at age was re-estimated in the 2014 assessment for 1975-1999 from primary databases maintained at AFSC. A simple non-stratified estimator was used, which consisted of compiling a single age-length key for use in every year and then applying the annual length composition to that key. Use of an age-length key was considered necessary because observers used length-stratified sampling designs to collect otoliths prior to 1999 (Barbeaux *et al.* 2005). Estimates were made separately for the foreign/JV and domestic fisheries in 1987 when both fisheries were sampled. There were no major discrepancies between the re-estimated age composition and estimates that have built up gradually from assessment to assessment.

Estimates of fishery age composition from 2000 onwards were derived from at-sea and port sampling of the pollock catch for length and ageing structures (otoliths). The length composition and ageing data were obtained from the NORPAC database maintained at AFSC. Catch age composition was estimated using methods described by Kimura and Chikuni (1989). Age samples were used to construct age-length keys by sex and stratum. These keys were applied to sex and stratum specific length frequency data to estimate age composition, which were then weighted by the catch in numbers in each stratum to obtain an overall age composition. A background age-length key is used fill the gaps in age-length keys by sex and stratum. Sampling levels by stratum for 2000-2015 are documented in the assessments available online at

| Time strata                | Туре           | Shumagin-<br>610 | Chirikof-<br>620 | Kodiak-<br>630 | W. Yakutat and PWS-640<br>and 649 |

http://www.afsc.noaa.gov/REFM/stocks/Historic\_Assess.htm. Age and length samples from the 2022 fishery were stratified by half-year seasons and statistical area as follows:

The dominant cohort in the 2023 expected age composition data was 2018 with 32%, followed by 2017 with 31%. The 2012 cohort is in the plus group and only accounts for about 13% of expected catch this year. Fishery catch at age in 1975-2022 is presented in Table 1.5 (see also Fig. 1.5). Sample sizes for ages and lengths are given in Table 1.6.

# Gulf of Alaska Bottom Trawl Survey

Trawl surveys have been conducted by Alaska Fisheries Science Center (AFSC) beginning in 1984 to assess the abundance of groundfish in the Gulf of Alaska (Tables 1.7 and 1.8). Starting in 2001, the survey frequency was increased from once every three years to once every two years. The survey uses a stratified random design, with 49 strata based on depth, habitat, and statistical area (Szalay *et al.* 2010). Area-swept biomass estimates are obtained using mean CPUE (standardized for trawling distance and mean net width) and stratum area. The survey is conducted from chartered commercial bottom trawlers using standardized poly-Nor'eastern high opening bottom trawls rigged with roller gear. In a full three-boat survey, 800 tows are completed, but the recent average has been closer to 600 tows. On average, 72% of these tows contain pollock (Table 1.8). Recent years have dropped stations in deeper water which are unlikely to affect the index due to pollock typically being in shallower depths with on average 90.9% below 200 m and 99.6% below 300 m from 1984-2021.

### **Biomass Estimates**

The time series of pollock biomass used in the assessment model is based on the surveyed area in the Gulf of Alaska west of 140° W long., obtained by adding the biomass estimates for the Shumagin-610, Chirikof-620, Kodiak-630 statistical areas, and the western portion of Yakutat-640 statistical area. Biomass estimates for the west Yakutat area were obtained by splitting strata and survey CPUE data at 140° W long. and re-estimating biomass for west Yakutat. In 2001, when the eastern Gulf of Alaska was not surveyed, a random effects model was used to interpolate a value for west Yakutat for use in the assessment model.

The Alaska Fisheries Science Center's (AFSC) Resource Assessment and Conservation Engineering (RACE) Division conducted the 18th comprehensive bottom trawl survey since 1984 during the summer of 2023 (Fig. 1.6). The 2023 gulfwide biomass estimate of pollock was 921,886 t, which is an increase of 74.3% from the 2021 estimate, which itself was a 72.2% increase from 2019, a sharp increase after the low in 2019. The biomass estimate for the portion of the Gulf of Alaska west of 140° W long. used in the assessment model is 887,602 t. The coefficient of variation (CV) of this estimate was 0.13, which is below the average of 0.197 for the entire time series. Surveys from 1990 onwards are used in the

assessment due to the difficulty in standardizing the surveys in 1984 and 1987, when Japanese vessels with different gear were used.

### **Age Composition**

Estimates of numbers at age from the bottom trawl survey are obtained from random otolith samples and length frequency samples (Table 1.8). Numbers at age are estimated by statistical area (Shumagin-610, Chirikof-620, Kodiak-630, Yakutat-640 and Southeastern-650) using a global age-length key for all strata in each single year, and CPUE-weighted length frequency data by statistical area. The 2023 ages were not yet available (Table 1.9), so instead 2023 length compositions were used (Fig. 1.7).

# **Shelikof Strait Acoustic Survey**

Winter acoustic surveys to assess the biomass of pre-spawning aggregations of pollock in Shelikof Strait have been conducted annually since 1981 (except 1982, 1987, 1999, and 2011). Only surveys from 1992 and later are used in the stock assessment due to the higher uncertainty associated with the acoustic estimates produced with the Biosonics echosounder used prior to 1992. Additionally, raw survey data are not easily recoverable for the earlier acoustic surveys, so there is no way to verify (i.e., to reproduce) the estimates. Survey methods and results for 2023 are presented in a NMFS processed report (McKelvey *et al.* in prep.). In 2008, the noise-reduced R/V Oscar Dyson became the designated survey vessel for acoustic surveys in the Gulf of Alaska. In winter of 2007, a vessel comparison experiment was conducted between the R/V Miller Freeman (MF) and the R/V Oscar Dyson (OD), which obtained an OD/MF ratio of 1.132 for the acoustic backscatter detected by the two vessels in Shelikof Strait.

### **Biomass Estimates**

The 2023 biomass estimate for Shelikof Strait in 2023 for all fish is 258,829 t, which is a 29% percent decrease from the 2022 estimate (Fig. 1.8). This estimate accounts for trawl selectivity by scaling up the number of retained pollock by selectivity curves estimated from previous years with pocket nets attached to the midwater trawl used to sample echosign. Winter 2023 pre-spawning pollock surveys were also conducted in the Shumagin Islands, Chirikof shelf break, Marmot Bay, Pavlov Bay, and Morzhovoi Bay. This contrasts with 2022 when the survey for the Shumagin Islands area was cancelled due to vessel mechanical issues, and the survey for the Shelikof area was delayed and reduced to just Shelikof Strait due to vessel mechanical issues and staffing constraints from the COVID-19 pandemic. Further information about the surveys conducted in 2023 can be found in McKelvey *et al.* (in prep.).

### **Age Composition**

Estimates of numbers at age from the Shelikof Strait acoustic survey (Table 1.10, Fig. 1.9) were obtained using an age-length key compiled from random otolith samples and applied to weighted length frequency samples. Sample sizes for ages and lengths are given in Table 1.11. Estimates of age composition in Shelikof Strait in 2023 indicate reduced, but persistent dominance of the 2012 year class, and a mode of age 4-6 fish, indicating new year classes are starting to comprise the majority of the spawning and exploitable portion of the population.

Based on recommendations from the 2012 CIE review, we developed an approach to model the age-1 and age-2 pollock estimates separately from the Shelikof Strait acoustic survey biomass and age composition. These immature fish are not the main target of the pre-spawning survey, but age-1 and age-2 pollock are highly variable and occasionally are very abundant in winter acoustic surveys. By fitting them separately from the 3+ fish it is possible to utilize an error distribution that better reflects that variability. Indices are available for both the Shelikof Strait and Shumagin surveys, but a longer time series of net-selectivity corrected indices are available for Shelikof Strait. In addition, model comparisons in the 2018 assessment

indicates that a slightly better fit could be obtained with only Shelikof Strait indices. Therefore this time series was used in the model, but this decision should be revisited as additional data become available.

The age-2 index in 2020 showed a marked reduction in comparison to the age-1 index in 2019, which indicated high abundance of the 2018 year class. Typically, year classes that are abundant in Shelikof Strait at age 1 are also abundant at age 2 in the survey the following year. The 2018 cohort comprised 15% of the age composition in 2021 (excluding age-1 and age-2 fish), but 29% as 4 year olds in 2022, giving contradictory evidence for marked decrease from initial estimates as age 1 fish. Consequently, there is considerable uncertainty regarding the fate of 2018 year class, which may have exited Shelikof Strait for some reason and be distributed elsewhere in the GOA, or suffered extremely high mortality. This point was addressed further in the risk table in the 2022 assessment (Monnahan *et al.* (2022)).

### Spawn timing and availability of pollock to the winter Shelikof survey

The Shelikof Strait winter acoustic survey is timed to correspond to the aggregation of pre-spawning pollock in Shelikof Strait. However, the timing of spawning has been found to vary from year to year, which may affect the availability of pollock to the survey. Variation in spawn timing is not random, but has been linked to thermal conditions in March and the age structure of the spawning stock (Rogers and Dougherty 2019); spawning tends to occur earlier when temperatures are warmer and when the spawning stock is older on average. Greater age diversity also results in a more protracted spawning period, presumably due to both early (old) and late (young) spawners, although this has not been verified in the field. A new approach to account for the timing of the survey relative to spawning was developed in 2022 and shows great promise, but was not put forward this year for consideration. Summaries of the work were presented to the Plan Team and further details can be found under the "Models under development" section of this document.

### **Summer Acoustic Survey**

Six complete acoustic surveys, in 2013, 2015, 2017, 2019, 2021 and 2023, have been conducted by AFSC on the R/V Oscar Dyson in the Gulf of Alaska during summer (Jones *et al.* in review, 2014, 2017, 2019; Levine *et al.* in prep.; McGowan *et al.* in prep.). The area surveyed covers the Gulf of Alaska shelf and upper slope and associated bays and troughs, from a westward extent of 170° W, and extends to an eastward extent of 140° W. Prince William Sound was also surveyed in 2013, 2015, and 2019. The survey consists of widely-spaced parallel transects along the shelf, and more closely spaced transects in troughs, bays, and Shelikof Strait. Mid-water and bottom trawls are used to identify acoustic targets. The 2023 biomass estimate for summer acoustic survey is 740,417 t, which is a 71.7% percent increase from the 2021 estimate (Table 1.7). Age compositions were not yet ready and so length compositions were used instead (Fig. 1.10). Analysis of the 2023 survey was not complicated by the presence of age-0 pollock, which was a problem in previous summer acoustic surveys because age-0 pollock backscatter cannot be readily distinguished from age 1+ pollock (Jones *et al.* 2019).

In 2023 an issue with vessel noise was identified and required a minor change in the way the data were processed. The processing methods used in the survey assume that noise is negligible. However, in 2023 there was concern that this was no longer the case due to recent changes in vessel noise (sonar self-noise at 38 kHz at survey speed was ~10 dB or ten-fold higher than in 2022). The effects of noise are depth and density dependent and are difficult to predict. Signal-to-noise thresholding and noise correction (De Robertis and Higginbottom 2007) was used to exclude pollock backscatter from areas influenced by noise (i.e., all areas with a signal-to-noise threshold of <6 dB were removed from the estimate). This revised processing resulted in total pollock biomass that was 0.19% less than for uncorrected data, confirming that noise had only a minor impact on the biomass estimate. Further details can be found in McGowan *et al.* (in prep.).

# Alaska Department of Fish and Game Crab/Groundfish Trawl Survey

The Alaska Department of Fish and Game (ADF&G) has conducted bottom trawl surveys of nearshore areas of the Gulf of Alaska since 1987 (depths from 9-137 m, median of 60 m in 2022; Fig. 1.11). Although these surveys are designed to monitor population trends of Tanner crab and red king crab, pollock and other fish are also sampled. Standardized survey methods using a 400-mesh eastern trawl were employed from 1987 to the present. The survey is designed to sample at fixed stations from mostly nearshore areas from Kodiak Island to Unimak Pass, and does not cover the entire shelf area (Fig. 1.11). The average number of tows completed during the survey is 353. On average, about 87% of these tows contained pollock. Details of the ADF&G trawl gear and sampling procedures are in Spalinger (2012).

The 2023 area-swept biomass estimate for pollock for the ADF&G crab/groundfish survey was 56,611 t, a decrease of 22.5% from the 2022 biomass estimate (Table 1.7). The 2023 pollock estimate for this survey is approximately 63% of the long-term average.

### **Biomass Estimates**

A delta GLM model was applied to the ADF&G tow by tow data for 1988-2023 to obtain annual abundance indices. Data from all years were filtered to exclude missing latitude and longitudes and missing tows made in lower Shelikof Strait (between 154.7° W lon. and 156.7° W lon.) were excluded because these stations were sampled irregularly. The delta GLM model fit a separate model to the presence-absence observations and to the positive observations. A fixed effects model was used with the year, geographic area, and depth as factors. Strata were defined according to ADF&G district (Kodiak, Chignik, South Peninsula) and depth (<30 fm, 30-100 fm, >100 fm). Alternative depth strata were evaluated previously, and model results were found to be robust to different depth strata assumptions. The same model structure was used for both the presence-absence observations and the positive observations. The assumed likelihoods were binomial for presence-absence observations and gamma for the positive observations, after evaluation of several alternatives, including lognormal, gamma, and inverse Gaussian, and which is in line with recommendations for index standardization (Thorson et al. 2021). The model was fit using 'brms' package in R (Bürkner 2017, 2018), which fits Bayesian non-linear regression models using the modeling framework Stan (Stan Development Team 2020). Comparison of delta-GLM indices the area-swept estimates indicated similar trends (Fig. 1.12). Variances were based on MCMC sampling from the posterior distribution, and CVs for the annual index ranged from 0.10 to 0.17. These values likely understate the uncertainty of the indices with respect to population trends, since the area covered by the survey is a relatively small percentage of the GOA shelf area, and so the CVs are scaled up to have an average of 0.25.

### **Age Compositions**

Ages were determined by age readers in the AFSC age and growth unit from samples of pollock otoliths collected during 2000- ADF&G surveys in even-numbered years (average sample size = 584; Table 1.12, Fig. 1.13). Comparison with fishery age composition shows that older fish (> age-8) are more common in the ADF&G crab/groundfish survey. This is consistent with the assessment model, which estimates a domed-shaped selectivity pattern for the fishery, but an asymptotic selectivity pattern for the ADF&G survey.

### Data sets considered but not used

### Egg production estimates of spawning biomass

Estimates of spawning biomass in Shelikof Strait based on egg production methods were produced during 1981-92 (Table 1.7). A complete description of the estimation process is given in Picquelle and Megrey

(1993). Egg production estimates were discontinued in 1992 because the Shelikof Strait acoustic survey provided similar information. The egg production estimates are also not used in the assessment model because the surveys are no longer being conducted, and because the acoustic surveys in Shelikof Strait show a similar trend over the period when both were conducted.

### Pre-1984 bottom trawl surveys

Considerable survey work was carried out in the Gulf of Alaska prior to the start of the NMFS triennial bottom trawl surveys in 1984. Between 1961 and the mid-1980s, the most common bottom trawl used for surveying was the 400-mesh eastern trawl. This trawl (or variants thereof) was used by IPHC for juvenile halibut surveys in the 1960s, 1970s, and early 1980s, and by NMFS for groundfish surveys in the 1970s. Szalay and Brown (2001) estimated a fishing power correction (FPC) for the ADF&G 400-mesh eastern trawl of 3.84 (SE = 1.26), indicating that 400-mesh eastern trawl CPUE for pollock would need to be multiplied by this factor to be comparable to the NMFS poly-Nor'eastern trawl.

In most cases, earlier surveys in the Gulf of Alaska were not designed to be comprehensive, with the general strategy being to cover the Gulf of Alaska west of Cape Spencer over a period of years, or to survey a large area to obtain an index for group of groundfish, i.e., flatfish or rockfish. For example, Ronholt *et al.* (1978) combined surveys for several years to obtain gulfwide estimates of pollock biomass for 1973-1976. There are several difficulties with such an approach, including the possibility of double-counting or missing a portion of the stock that happened to migrate between surveyed areas. Due to the difficulty in constructing a consistent time series, the historical survey estimates are no longer used in the assessment model.

Multi-year combined survey estimates indicate a large increase in pollock biomass in the Gulf of Alaska occurred between the early 1960s and the mid 1970s. Increases in pollock biomass between the 1960s and 1970s were also noted by Alton *et al.* (1987). In the 1961 survey, pollock were a relatively minor component of the groundfish community with a mean CPUE of 16 kg/hr (Ronholt *et al.* 1978). Arrowtooth flounder was the most common groundfish with a mean CPUE of 91 kg/hr. In the 1973-76 surveys, the CPUE of arrowtooth flounder was similar to the 1961 survey (83 kg/hr), but pollock CPUE had increased 20-fold to 321 kg/hr, and was by far the dominant groundfish species in the Gulf of Alaska. Mueter and Norcross (2002) also found that pollock was low in the relative abundance in 1960s, became the dominant species in Gulf of Alaska groundfish community in the 1970s, and subsequently declined in relative abundance.

Questions concerning the comparability of pollock CPUE data from historical trawl surveys with later surveys probably can never be fully resolved. However, because of the large magnitude of the change in CPUE between the surveys in the 1960s and the early 1970s using similar trawling gear, the conclusion that there was a large increase in pollock biomass seems robust. Early speculation about the rise of pollock in the Gulf of Alaska in the early 1970s implicated the large biomass removals of Pacific ocean perch, a potential competitor for euphausiid prey (Somerton 1979; Alton *et al.* 1987). More recent work has focused on role of climate change (Anderson and Piatt 1999; Bailey 2000). These earlier surveys suggest that population biomass in the 1960s, prior to large-scale commercial exploitation of the stock, may have been lower than at any time since then.

# **Qualitative Trends**

To qualitatively assess recent trends in abundance, each survey time series was standardized by dividing the annual estimate by the average since 1990. Shelikof Strait acoustic survey estimates prior to 2008 were rescaled to be comparable to subsequent surveys conducted by the R/V Oscar Dyson. Although the indices are not directly comparable due to selectivity differences and the considerable variability in each survey time series, a fairly clear downward trend is evident to 2000, followed by a stable, though variable,

trend to 2008, followed by a strong increase to 2013 (Fig. 1.14). From 2016 to 2019 there was a strong divergence among the trends, but the relative abundance came back into reasonable alignment from 2020-2023 with the exception of the large estimate of the NMFS bottom trawl survey in 2023.

Indices derived from fisheries catch data were also evaluated for trends in biological characteristics (Fig. 1.15). The percent of females in the catch shows some variability and generally is close to 50-50, but has been low since 2015. Evaluation of sex ratios by season indicated that this decrease was mostly due a low percentage of females during the A and B seasons (now the A season) prior to spawning. However the sex ratio during the C and D (now the B season) seasons was close to 50-50, suggesting the skewed sex in winter was related to spawning behavior, rather than an indication of a population characteristic. The mean age shows interannual variability due to strong year classes passing through the population, but there are no downward trends that would suggest excessive mortality rates. The percent of old fish in the catch (nominally defined as age 8 and older) is also highly variable due to variability in year class strength. The percent of old fish declined in 2015-2018 as the strong 2012 year class recruited to the fishery, but increased when the 2012 year class became age 8 in 2020. With large incoming cohorts and the decline of the 2012 cohort, the mean age has begun to decrease again. Under a constant F40% harvest rate, the mean percent of age 8 and older fish in the catch would be approximately 8%.

An annual index of catch at age diversity was computed using the Shannon-Wiener information index, H', defined as

$$H' = -\sum_{a} p_{a} \ln p_{a}$$

where  $p_a$  is the proportion at age and higher values correspond to higher diversity. Increases in fishing mortality would tend to reduce age diversity, but year class variability would also influence it. Age diversity was relatively stable during 1975-2015, but declined sharply to a low in 2016 and has been increasing since due to the dominance of the 2012 year class in the catch (Fig. 1.15). In 2021 the age diversity returned to near the long-term average and remains there through 2023.

The 2012 year class, which is both very strong, and which has experienced anomalous environmental conditions during the marine heatwave in the North Pacific during 2015-2017, has displayed unusual life history characteristics. These include early maturation, reduced growth, but apparently not reduced total mortality. It is unclear whether these changes are a result of density dependence or environmental forcing. Previous assessments examined this cohort in more depth, but its impact on the fishery is diminishing and is not a focus here.

# **Analytical approach**

### **General Model Structure**

An age-structured model covering the period from 1970 to 2023 (54 years) was used to assess Gulf of Alaska pollock. The modeled population includes individuals from age 1 to age 10, with age 10 defined as a "plus" group, i.e., all individuals age 10 and older. Population dynamics were modeled using standard formulations for mortality and fishery catch (e.g., Fournier and Archibald 1982; Deriso *et al.* 1985; Hilborn and Walters 1992). Year- and age-specific fishing mortality was modeled as a product of a year effect, representing the full-selection fishing mortality, and an age effect, representing the selectivity of that age group to the fishery. The age effect was modeled using a double-logistic function with time-varying parameters (Dorn and Methot 1990; Sullivan *et al.* 1997). The model was fit to time series of catch biomass, survey indices of abundance, and estimates of age and length composition from the fishery and surveys. Details of the population dynamics and estimation equations are presented in Appendix 1C.

Model parameters were estimated by maximizing the joint log likelihood of the data and penalties, viewed as a function of the parameters. Mean-unbiased log-normal likelihoods were used for survey biomass and total catch estimates, and multinomial likelihoods were used for age and length composition data. Model tuning for composition data was done by iterative re-weighting of input sample sizes using the Francis (2011) method. Variance estimates/assumptions for survey indices were not reweighted. The following table lists the likelihood components used in fitting the model.

| Likelihood component   | Statistical model for error | Variance assumption  |
|--|-----------------------------|--|
| Fishery total catch (1970-2023)                              | Log-normal                  | CV = 0.05, 2023 catch is projected   |
| Fishery age comp. (1975-2022)                                | Multinomial                 | Initial sample size: 200 or the number of tows/deliveries if less than 200 |
| Shelikof acoustic survey biomass (1992-2023)                 | Log-normal                  | CV = 0.20  |
| Shelikof acoustic survey age comp. (1992-2023)               | Multinomial                 | Initial sample size $= 60$   |
| Shelikof acoustic survey age-1 and age-2 indices (1994-2023) | Log-normal                  | Tuned $CVs = 0.45$ and $0.55$  |
| Summer acoustic survey biomass (2013-2023)                   | Log-normal                  | CV = 0.25  |
| Summer acoustic survey age comp. (2013-2021)                 | Multinomial                 | Initial sample size = 10   |
| NMFS bottom trawl survey biom. (1990-2023)                   | Log-normal                  | Survey-specific CV from random-stratified design $= 0.12-0.38$             |
| NMFS bottom trawl survey age comp. (1990-2021)               | Multinomial                 | Initial sample size $= 60$   |
| ADF&G trawl survey index (1989-2023)                         | Log-normal                  | Survey-specific CV from delta GLM model rescaled so mean is 0.25=0.20-0.35 |
| ADF&G survey age comp. (2000-2022)                           | Multinomial                 | Initial sample size = 30   |
| Recruit process error (1970-2023)                            | Log-normal                  | Penalty of 1.3 (updated in 2022 model 19.1a)                               |

### Recruitment

Age composition in the first year is estimated with a single log deviation for recruitment abundance, which was then decremented by natural mortality to fill out the initial age vector. In previous versions of the model, a recruitment penalty of ( $\sigma_R = 1.0$ ) was added only to recruitments for 1970-77, and in the last two years of the model and the rest were were estimated as free parameters. Starting in 2022 with model 19.1a the penalty was applied to all deviations, with a value of  $\sigma_R = 1.3$  coming from an estimate of a state-space research version of the model. This change had a relatively small impact on the estimated recruits and management reference points.

### Modeling fishery data

To accommodate changes in selectivity, we estimated year-specific parameters for the slope and the intercept parameter for the ascending logistic portion of selectivity curve (i.e., younger fish). Variation in these parameters was constrained using a random walk penalty.

### Modeling survey data

Survey abundance was assumed to be proportional to total abundance as modified by the estimated survey selectivity pattern. Expected population numbers at age for the survey were based on the mid-date of the survey, assuming constant fishing and natural mortality throughout the year. Standard deviations in the

log-normal likelihood were set equal to the sampling error CV (coefficient of variation) associated with each survey estimate of abundance (Kimura 1991).

Survey catchability coefficients can be fixed or freely estimated. The base model estimated the NMFS bottom trawl survey catchability, but used a log normal prior with a median of 0.85 and log standard deviation 0.1 based on expert judgment as a constraint on potential values (Fig. 1.16). Catchability coefficients for other surveys were estimated as free parameters. The age-1 and age-2 winter acoustic survey indices are numerical abundance estimates, and were modeled using independently estimated catchability coefficients (i.e., no selectivity is estimated).

A vessel comparison (VC) experiment was conducted in March 2007 during the Shelikof Strait acoustic survey. The VC experiment involved the R/V Miller Freeman (MF, the survey vessel used to conduct Shelikof Strait surveys since the mid-1980s), and the R/V Oscar Dyson (OD), a noise-reduced survey vessel designed to conduct surveys that have traditionally been done with the R/V Miller Freeman. The vessel comparison experiment was designed to collect data either with the two vessels running beside one another at a distance of 0.7 nmi, or with one vessel following nearly directly behind the other at a distance of about 1 nmi. The methods were similar to those used during the 2006 Bering Sea VC experiment (Robertis *et al.* 2008). Results indicate that the ratio of 38 kHz pollock backscatter from the R/V Oscar Dyson relative to the R/V Miller Freeman was significantly greater than one (1.13), as would be expected if the quieter OD reduced the avoidance response of the fish. Previously we included a likelihood component to incorporate this information in the assessment model, but dropped it because this survey is now modeled with a random walk in catchability, and a relatively small systematic change in catchability is inconsequential compared to other factors affecting catchability.

### Ageing error

An ageing error conversion matrix is used in the assessment model to translate model population numbers at age to expected fishery and survey catch at age (Table 1.13). Dorn *et al.* (2003) estimated this matrix using an ageing error model fit to the observed percent reader agreement at ages 2 and 9. Mean percent agreement is close to 100% at age 1 and declines to 40% at age 10. Annual estimates of percent agreement are variable, but show no obvious trend; hence a single conversion matrix for all years in the assessment model was adopted. The model is based on a linear increase in the standard deviation of ageing error and the assumption that ageing error is normally distributed. The model predicts percent agreement by taking into account the probability that both readers are correct, both readers are off by one year in the same direction, and both readers are off by two years in the same direction (Methot 2000). The probability that both agree and were off by more than two years was considered negligible. A study evaluated pollock ageing criteria using radiometric methods and found them to be unbiased (Kastelle and Kimura 2006).

### Length frequency data

The assessment model was fit to length frequency data from various sources by converting predicted age distributions (as modified by age-specific selectivity) to predicted length distributions using an age-length conversion matrix. This approach was used only when age composition estimates were unavailable, as occurs when the survey is the same as the assessment. Because seasonal differences in pollock length at age are large, particularly for the younger fish, several conversion matrices were used. For each matrix, unbiased length distributions at age were estimated for several years using age-length keys, and then averaged across years. A conversion matrix was estimated using 1992-1998 Shelikof Strait acoustic survey data and used for winter survey length frequency data. The following length bins were used: 5-16, 17-27, 28-35, 36-42, 43-50, 51-55, 56-70 (cm). Age data for the most recent survey is now routinely available so this option does not need to be invoked. A conversion matrix was estimated using second and third trimester fishery age and length data during the years (1989-1998), and was used when age

composition data are unavailable for the summer bottom trawl survey, which is only for the most recent survey in the year that the survey is conducted. The following length bins were used: 5-24, 25-34, 35-41, 42-45, 46-50, 51-55, 56-70 (cm), so that the first four bins would capture most of the summer length distribution of the age-1, age-2, age-3 and age-4 fish, respectively. Bin definitions were different for the summer and the winter conversion matrices to account for the seasonal growth of the younger fish (ages 1-4).

### Initial data weighting

The input sample sizes were initially standardized by data set before model tuning. Fishery age composition was given an initial sample size of 200 except when the age sample in a given year came from fewer than 200 hauls/deliveries, in which case the number of hauls/deliveries was used. Both the Shelikof acoustic survey and the bottom trawl age compositions were given an initial sample size of 60, and the ADF&G crab/groundfish survey was given a weight of 30.

## Parameters Estimated Outside the Assessment Model

Pollock life history characteristics, including natural mortality, weight at age, and maturity at age, were estimated independently outside the assessment model. These parameters are used in the model to estimate spawning and population biomass and obtain predictions of fishery catch and survey biomass. Pollock life history parameters include:

- Natural mortality (*M*)
- Proportion mature at age
- Weight at age and year by fishery and by survey

### Natural mortality

Hollowed and Megrey (1990) estimated natural mortality (M) using a variety of methods including estimates based on: a) growth parameters (Alverson 1975; Pauly 1980), b) GSI (Gunderson and Dygert 1988), c) monitoring cohort abundance, and d) estimation in the assessment model. These methods produced estimates of natural mortality that ranged from 0.22 to 0.45. The maximum age observed was 22 years. Up until the 2014 assessment, natural mortality had been assumed to be 0.3 for all ages.

Hollowed et al. (2000) developed a model for Gulf of Alaska pollock that accounted for predation mortality. The model suggested that natural mortality declines from 0.8 at age 2 to 0.4 at age 5, and then remains relatively stable with increasing age. In addition, stock size was higher when predation mortality was included. In a simulation study, Clark (1999) evaluated the effect of an erroneous M on both estimated abundance and target harvest rates for a simple age-structured model. He found that "errors in estimated abundance and target harvest rate were always in the same direction, with the result that, in the short term, extremely high exploitation rates can be recommended (unintentionally) in cases where the natural mortality rate is overestimated and historical exploitation rates in the catch-at-age data are low." Clark (1999) proposed that the chance of this occurring could be reduced by using an estimate of natural mortality on the lower end of the credible range, which is the approach used in this assessment. In the 2014 assessment, several methods to estimate of the age-specific pattern of natural mortality were evaluated. Two general types of methods were used, both of which are external to the assessment model. The first type of method is based initially on theoretical life history or ecological relationships that are then evaluated using meta-analysis, resulting in an empirical equation that relates natural mortality to some more easily measured quantity such as length or weight. The second type of method is an agestructured statistical analysis using a multispecies model or single species model where predation is modeled. There are three examples of such models for pollock in Gulf of Alaska, a single species model with predation by Hollowed et al. (2000), and two multispecies models that included pollock by Kirk

(2010, 2012). These models were published in the peer-reviewed literature, but likely did not receive the same level of scrutiny as stock assessment models. Although these models also estimate time-varying mortality, we averaged the total mortality (residual natural mortality plus predation mortality) for the last decade in the model to obtain a mean age-specific pattern (in some cases omitting the final year when estimates were much different than previous years). Use of the last decade was an attempt to use estimates with the strongest support from the data. Approaches for inclusion of time-varying natural mortality will be considered in future pollock assessments. The three theoretical/empirical methods used were the following:

Brodziak et al. (2011): Age-specific M is given by

$$M(a) = \begin{cases} M_c \frac{L_{mat}}{L(a)} & \text{for } a < a_{mat} \\ M_c & \text{for } a \ge a_{mat} \end{cases}$$

where  $L_{mat}$  is the length at maturity,  $M_c = 0.30$  is the natural mortality at  $L_{mat}$ , L(a) is the mean length at age for the summer bottom trawl survey for 1984-2013.

Lorenzen (1996): Age-specific M for ocean ecosystems is given by

$$M(a) = \bar{W_a}^{-0.305}$$

where  $W_a$  is the mean weight at age from the summer bottom trawl survey for 1984-2013.

Gislason et al. (2010): Age-specific M is given by

$$\ln(M) = 0.55 - 1.61\ln(L) + 1.44\ln(L_{\infty}) + \ln K$$

where  $L_{\infty} = 65.2$  cm and K = 0.30 were estimated by fitting von Bertalanffy growth curves using the NLS routine in R using summer bottom trawl age data for 2005-2009 for sexes combined in the central and western Gulf of Alaska. Results were reasonably consistent and suggest use of a higher mortality rate for age classes younger than the age at maturity (Table 1.14 and Fig. 1.17). Somewhat surprisingly, the theoretical/empirical estimates were similar, on average, to predation model estimates. To obtain an age-specific natural mortality schedule for use in the stock assessment, we used an ensemble approach and averaged the results for all methods. Then we used the method recommended by Clay Porch in Brodziak *et al.* (2011) to rescale the age-specific values so that the average for range of ages equals a specified value. Age-specific values were rescaled so that a natural mortality for fish greater than or equal to age 5, the age at 50% maturity, was equal to 0.3, the value of natural mortality used in previous pollock assessments.

#### Maturity at age

Maturity stages for female pollock describe a continuous process of ovarian development between immature and post-spawning. For the purposes of estimating a maturity vector (the proportion of an age group that has been or will be reproductively active during the year) for stock assessment, all fish greater than or equal to a particular maturity stage are assumed to be mature, while those less than that stage are assumed to be immature. Maturity stages in which ovarian development had progressed to the point where ova were distinctly visible were assumed to be mature (i.e., stage 3 in the 5-stage pollock maturity scale). Maturity stages are qualitative rather than quantitative, so there is subjectivity in assigning stages, and a potential for different technicians to apply criteria differently (Neidetcher et al. 2014). Because the link between pre-spawning maturity stages and eventual reproductive activity later in the season is not well established, the division between mature and immature stages is problematic. Changes in the timing of spawning could also affect maturity at age estimates. Merati (1993) compared visual maturity stages

with ovary histology and a blood assay for vitellogenin and found general consistency between the different approaches. Merati (1993) noted that ovaries classified as late developing stage (i.e., immature) may contain yolked eggs, but it was unclear whether these fish would have spawned later in the year. The average sample size of female pollock maturity stage data per year since 2000 from winter acoustic surveys in the Gulf of Alaska is 372 (Table 1.15). In 2019, a new approach was introduced to estimate maturity at age using specimen data from the Shelikof Strait acoustic survey. Maturity estimates from 2003 onwards were revised using this method. The approach uses local abundance to weight the maturity data collected in a haul. To estimate abundance, each acoustic survey distance unit (0.5 nmi of trackline) was assigned to a stratum representing nearest survey haul. Each haul's biological data was then used to scale the corresponding acoustic backscatter within that stratum into abundance. To generate abundance weights for specimen data taken for each haul location, the abundance estimates of adult pollock ( $\geq 30$ cm fork length) were summed for each haul-stratum. The 30 cm length threshold represents the length at which pollock are 5% mature in the entire Shelikof Strait historic survey data. Total adult pollock abundances in each stratum was scaled by dividing by the mean abundance per stratum (total abundance /number of haul-strata). Weights range from 0.05 to 6, as some hauls were placed in low-density regions while others sampled very dense aggregations. For each haul, the number of female pollock considered mature (prespawning, spawning, or spent) and immature (immature or developing) were computed for each age. The maturity ogive for maturity-at-age was estimated as a logistic regression using a weighted generalized linear model where the dependent variable was the binomial spawning state, the independent variable was the age, and data from each haul were weighted by the appropriate values as computed above. The length and age at 50% maturity was derived (L50%, A50%) from the ratio of the regression coefficients. The new maturity estimates had a relatively minor impact on assessment results, and usually reduced estimates of spawning biomass by about 2 percent. Estimates of maturity at age in 2022 from winter acoustic surveys using the new method are higher for younger fish, but lower for older fish, compared to 2021 and the long-term mean for all ages (Fig. 1.18 and 1.19). Inter-annual changes in maturity at age may reflect environmental conditions, pollock population biology, effect of strong year classes moving through the population, or simply ageing error. Because there did not appear to be an objective basis for excluding data, the 1983-2021 average maturity at age was used in the assessment.

Logistic regression (McCullagh and Nelder 1983) was also used to estimate the age and length at 50% maturity at age for each year to evaluate long-term changes in maturation. Annual estimates of age at 50% maturity are highly variable and range from 2.6 years in 2017 to 6.1 years in 1991, with an average of 4.8 years (Fig. 1.20). The last few years has shown a decrease in the age at 50% mature, which is largely being driven by the maturation of the 2012 year class at younger ages than is typical, however the 2019 to 2022 estimates of age at 50% mature, suggesting that at least some of the variability in the age at maturity can be attributed to changes in length at age. Changes in year-class dominance also likely affect estimates of maturity at length, as a similar pattern is seen as with maturity at age with the 2012 cohort. The average length at 50% mature for all years is approximately 43 cm.

### Weight at age

Year-specific fishery weight-at-age estimates are used in the model to obtain expected catches in biomass. Where possible, year and survey-specific weight-at-age estimates are used to obtain expected survey biomass. For each data source, unbiased estimates of length at age were obtained using year-specific age-length keys. Bias-corrected parameters for the length-weight relationship,  $W = aL^b$ , were also estimated. Weights at age were estimated by multiplying length at age by the predicted weight based on the length-weight regressions. Weight at age for the fishery, the Shelikof Strait acoustic survey, and the NMFS bottom trawl survey and the summer acoustic survey are given in Tables 1.16, 1.17, and 1.18. Data from the Shelikof Strait acoustic survey indicates that there has been a substantial change in weight at age for older pollock (Fig. 1.21). For pollock greater than age 6, weight-at-age nearly doubled by 2012 compared

to 1983-1990. However, weight at age trended strongly downward from 2012 to 2020, with some rebound in the last couple of years. Further analyses are needed to evaluate whether these changes are a density-dependent response to declining pollock abundance, or whether they are environmentally forced. Changes in weight-at-age have important implications for status determination and harvest control rules.

A random effects (RE) model for weight at age (Ianelli *et al.* 2016) was used to estimate of fishery weight at age in 2023 since age data were not available. The structural part of the model is an underlying von Bertalanffy growth curve. Year and cohort effects are estimated as random effects using the ADMB RE module. Further details are provided in Ianelli *et al.* (2016). Input data included fishery weight age for 1975-2022. The model also incorporates survey data by modeling an offset between fishery and survey weight at age. Weight at age for the Shelikof Strait acoustic survey (1981-2023) and the NMFS bottom trawl survey (1984-2021) were used. The model also requires input standard deviations for the weight at age data, which are not available for GOA pollock. In the 2016 assessment, a generalized variance function was developed using a quadratic curve to match the mean standard deviations at ages 3-10 for the eastern Bering Sea pollock data. The standard deviation at age one was assumed to be equal to the standard deviation at age 10. Survey weights at age were assumed to have standard deviations that were 1.5 times the fishery weights at age. A comparison of RE model estimates from last year of the 2022 fishery weight at age with the data now available indicate that the model overestimated weights slightly (Fig. 1.22). In this assessment, RE model estimates of weight at age are used for the fishery in 2023 and for yield projections and harvest recommendations.

Correa *et al.* (2023) details an exploratory and promising approach using a state-space model to estimate the WAA within the assessment model and this will be explored further in future years.

### **Parameters Estimated Inside the Assessment Model**

A large number of parameters are estimated when using this modeling approach, though many are yearspecific deviations in fishery selectivity coefficients. Parameters were estimated using Template Model Builder [TMB; Kristensen *et al.* (2016)], a modeling platform based strongly on AD Model Builder (Fournier *et al.* 2012) but which contains improved functionality for estimating non-linear hierarchical models. The model is determined to have converged when the maximum parameter gradient is less than a small constant (set to 1 x 10-6) and the Hessian matrix is invertible. Like AD Model Builder, TMB includes post-convergence routines to calculate standard errors (or likelihood profiles) for any quantity of interest, and has state of the art Bayesian integration capabilities (Monnahan and Kristensen 2018).

| Population process modeled            | Number of parameters    | Estimation details  |
|---------------------------------------|-------------------------|---|
| Mean recruitment                      | 1                       | Estimated in log space  |
| Recruitment deviations                | Years 1970-2023 = 54    | Estimated as log deviances from the log mean with all years constrained by random deviation process error of 1.3.                 |
| Natural mortality                     | Age-specific= 10        | Not currently estimated in the model  |
| Fishing mortality                     | Years 1970-2023 = 54    | Estimated as log deviances from the log mean  |
| Mean fishery selectivity              | 4                       | Slope parameters estimated on a log scale, intercept parameters on an arithmetic scale  |
| Annual changes in fishery selectivity | 2 * (No. years-1) = 108 | Estimated as deviations from mean selectivity and constrained by random walk process error  |
| Mean survey catchability              | No. of surveys $= 6$    | Catchabilities estimated on a log scale. Separate catchabilities were also estimated for age-1 and age-2 winter acoustic indices. |

A list of model parameters for the base model is shown below:

| Population process<br>modeled         | Number of parameters   | Estimation details   |
|---------------------------------------|--|--|
| Annual changes in survey catchability | 2 * (No. years-1) = 108  | Annual catchability for winter acoustic surveys and<br>ADF&G surveys estimated as deviations from mean<br>catchability and constrained by random walk process<br>error |
| Survey selectivity                    | 8 (2 each for the Shelikof and<br>summer acoustic surveys, and the<br>NMFS and ADF&G BT surveys) | Slope parameters estimated on a log scale.   |
| Total                                 | 123 estimated parameters + 216<br>process errors = 339   |  |

## Model selection and evaluation

### **Model selection**

Prior to identifying a model for consideration, an analysis was conducted of the impact of each new data element on model results. Figure 1.23 shows the changes in estimated spawning biomass as the updated catch projections, catch at age, and surveys were added sequentially. This year, additions changed both the trend and scale of the stock. In particular adding the NMFS BT index and lengths, the Shelikof index and ages, and summer acoustic index all substantially increased the estimate of stock size. Such changes are not typical, but given the large increases in survey indices it is not entirely surprising that recent trends shifted upward. Likewise, a change in scale is expected given the known sensitivity for this model to changes in data and model assumptions (as explored more thoroughly in e.g., Monnahan *et al.* (2021)) and the Plan Team presentations in 2022 (link to pdf).

The intent of this year's assessment was to migrate to the new TMB modeling framework without considering any changes to the model structure. Conversion requires a substantial effort not only in rewriting the C++ model, but also the workflow for processing model inputs and results. After adding new data to model 23.0, a final turning step was done using the Francis (2011) approach which reweighted all composition components, including the summer acoustic age composition for the second time, resulting in the only downward estimate of SSB in the model results (Fig. 1.23).

### **Model evaluation**

The fit of model 23.0 to age composition data was evaluated using plots of observed and predicted age composition and residual plots. Figure 1.24 shows the estimates of time-varying catchability for the Shelikof Strait acoustic survey and the ADF&G crab/groundfish survey, as well as the constant catchabilities for the other surveys. The catchability for the Shelikof Strait acoustic survey continued to decrease away from 1, and is close to 0.5 in 2023. Catchability for the NMFS bottom trawl and summer acoustic surveys were similar (0.80 and 0.70 respectively), while the age-1 and age-2 Shelikof survey catchabilities were 0.22 and 0.26, respectively, reflecting the fact that the survey does not target these immature ages.

One-step-ahead (OSA) residuals are used this year to assess fits to composition data (Trijoulet *et al.* 2023). Plots show the fit to fishery age composition (Figs. 1.25, 1.26), Shelikof Strait acoustic survey age composition (Figs. 1.27,1.28), NMFS trawl survey age composition (Fig. 1.29), ADF&G trawl survey age composition (Fig. 1.30) and the summer acoustic survey (Fig. 1.31). Model fits to fishery age composition data are adequate in most years, though the very strong 2012 year class shows up as a positive residual in 2016-2023 due to stronger than expected abundance in the age composition. Previous

assessments had strong patterns of negative residuals for older ages, but it is clear now using OSA residuals that these were not real and instead an artifact of Pearson residuals being wrong. In contrast, the pattern of negative residuals for age 4 and positive for age 3 persists with OSA residuals, suggesting these are real. More complicated selectivity forms were able to eliminate this pattern (Appendix 1F). The NMFS bottom trawl survey has relatively good residuals, even for the most recent years where there is a misfit in the index. The ADF&G compositions overall do not fit well, exhibiting strong patterns of positive residuals after 2000. The two acoustic surveys had no apparent issues fitting to the data. Overall there were no major issues in fitting the age composition data and the issues highlighted here are considered minor.

In recent assessments there was apparent conflict and uncertainty in the data about the size of the 2018 cohort. The new estimate of the initial cohort size is about 8 billion fish, larger than average (Table 1.19), an increase from 5.4 billion in the previous assessment. This appears to confirm that this cohort was relatively large and for unknown reasons was not apparent in previous years of data.

Model fits to survey biomass estimates are reasonably good for all surveys except the period 2015-2019 and now in 2023 with poor fits to the 2023 Shelikof winter acoustic survey and NMFS bottom trawl surveys (Fig. 1.32). The lack of fit in the NMFS bottom trawl survey from 2015 to 2023 is a major concern and discussed in the context of the risk table below. In addition, the model is unable to fit the extremely low values for the ADF&G survey in 2015-2017. The fit to the summer acoustic survey is reasonable even during the most recent period. The model shows good fits to both the 2021 Shelikof Strait acoustic survey and the 2021 NMFS bottom trawl, while the 2021 ADF&G bottom trawl and 2021 summer acoustic survey fits were reasonable. The fit to the age-1 and age-2 Shelikof acoustic indices was considered acceptable with a few exceptions (Fig. 1.33).

# **Time series results**

Parameter estimates and model output are presented in a series of tables and figures. Estimated survey and fishery selectivity for different periods are given in Table 1.20 (see also Figs. 1.34 and 1.35. Table 1.21 gives the estimated population numbers at age for the years 1970-2023. Table 1.19 gives the estimated time series of age 3+ population biomass, age-1 recruitment, status, and harvest rate (catch/3+ biomass) for 1977-2023 (see also Fig. 1.36). Table 1.22 gives coefficients of variation and 95% confidence intervals for age-1 recruitment and spawning stock biomass.

Stock size peaked in the early 1980s at approximately 103% of the proxy for unfished stock size (B100% = mean 1978- 2022 recruitment multiplied by the spawning biomass per recruit in the absence of fishing (SPR at F=0), see below for how this is calculated). In 2002, the stock dropped below B40% for the first time since the early 1980s, and reached a minimum in 2003 of 35% of unfished stock size. Over the years 2009-2013 stock size showed a strong upward trend, increasing from 45% to 88% of unfished stock size, but declined to 65% of unfished stock size in 2015. The spawning stock peaked in 2017 at 90% as the strong 2012 year class matured, and has declined subsequently to 68% in 2023. Figure 1.37 shows the historical pattern of exploitation of the stock both as a time series of SPR and fishing mortality compared to the current estimates of biomass and fishing mortality reference points. Except from the mid-1970s to mid-1980s fishing mortalities have generally been lower than the current OFL definition, and in nearly all years were lower than the FMSY proxy of F35%.

# **Comparison of historical assessment results**

A comparison of assessment results for the years 1999-2023 indicates the current estimated trend in spawning biomass for 1990-2023 is consistent with previous estimates (Table 1.24 and Fig. 1.38). All time series show a similar pattern of decreasing spawning biomass in the 1990s, a period of greater stability in 2000s, followed by an increase starting in 2008. The estimated 2023 age composition from the

current assessment was very similar to the projected 2023 age composition from the 2022 assessment (Fig. 1.39). Generally, the two models agree except for the age 1 recruits, where the 2022 model assumed average recruitment, but the 2023 model has data from the Shelikof survey which showed a weak 2022 year class. This difference does not strongly affect the OFL and ABC for next year because these fish are not in the exploitable population.

## Retrospective analysis of base model

A retrospective analysis consists of dropping the data year-by-year from the current model, and provides an evaluation of the stability of the current model as new data are added. Figure 1.40 shows a retrospective plot with data sequentially removed back to 2016. The range of errors in the estimates of spawning biomass (if the current assessment is accepted as truth) is -37.7% to -24.8%, but usually the errors are much smaller (median absolute error is -33%). There is a relatively large negative retrospective pattern in the assessment (i.e., the model consistently underestimates SSB), and the revised Mohn's  $\rho$ (Mohn 1999) across all seven peels for terminal spawning biomass is -0.308. This is considered a significant  $\rho$  based on a bootstrapping analysis done on the 2022 assessment which found that by chance  $\rho$  would be between -0.21 and 0.29 (Bryan and Monnahan in prep), and is worse than in recent years. Trends in estimates of cohort sizes is also given in Fig. 1.41.

# **Stock productivity**

Recruitment of GOA pollock is more variable (CV = 1.3 over 1978-2022) than Eastern Bering Sea pollock (CV = 0.60). Other North Pacific groundfish stocks, such as sablefish and Pacific ocean perch, also have high recruitment variability. However, unlike sablefish and Pacific ocean perch, pollock have a short generation time (~8 years), so that large year classes do not persist in the population long enough to have a buffering effect on population variability. Because of these intrinsic population characteristics, the typical pattern of biomass variability for GOA pollock will be sharp increases due to strong recruitment, followed by periods of gradual decline until the next strong year class recruits to the population. GOA pollock is more likely to show this pattern than other groundfish stocks in the North Pacific due to the combination of a short generation time and high recruitment variability.

Since 1980, strong year classes have occurred periodically every four to six years (Fig. 1.36). Because of high recruitment variability, the mean relationship between spawning biomass and recruitment is difficult to estimate despite good contrast in spawning biomass. Strong and weak year classes have been produced at high and low level of spawning biomass. Spawner productivity is higher on average at low spawning biomass compared to high spawning biomass, indicating that survival of eggs to recruitment is density-dependent (Fig. 1.42). However, this pattern of density-dependent survival only emerges on a decadal scale, and could be confounded with environmental variability on the same temporal scale. The decadal trends in spawner productivity have produced the pattern of increase and decline in the GOA pollock population. The last two decades have been a period of relatively low spawner productivity, though there appears to be a recent increase. Age-1 recruitment in 2022 and 2023 is estimated to be to be very weak, but the 2021 recruitment is above average, although these estimates will remain very uncertain until additional data become available (Figure 1.36).

# **Harvest Recommendations**

### Reference fishing mortality rates and spawning biomass levels

Since 1997, GOA pollock have been managed under Tier 3 of the NPFMC tier system. In Tier 3, reference mortality rates are based on spawning biomass per recruit (SPR), while biomass reference levels

are estimated by multiplying the SPR by average recruitment. Estimates of the FSPR harvest rates were obtained using the life history characteristics of GOA pollock (Table 1.23). Spawning biomass reference levels were based on mean 1978-2022 age-1 recruitment (6.297 billion), which is 2.6% higher than the mean value in last year's assessment. Spawning was assumed to occur on March 15th, and a long-term average of maturity at age (1983- 2023) was used with mean spawning weight at age from the Shelikof Strait acoustic surveys in 2019-2023 to estimate current reproductive potential. Fishery weight at age was assumed to be the most recent estimate from the RE model. Pollock weight-at-age is highly variable, showing a sustained increase, followed by a steep decline until a sharp increase from 2020 to 2023 (Fig. 1.21). The factors causing this pattern are unclear, but are likely to involve both density-dependent factors and environmental forcing. The SPR at F=0 was estimated as 0.076 kg/recruit at age one. FSPR rates depend on the selectivity pattern of the fishery. Selectivity has changed as the fishery evolved from a foreign fishery occurring along the shelf break to a domestic fishery on spawning aggregations and in nearshore waters. For SPR calculations, selectivity was based on the average for 2019 - 2022 to reflect current selectivity patterns. GOA pollock FSPR harvest rates are given below:

| FSPR   | Fishing   | Avg. Recr. | Total 3+ biomass | SSB  | Catch | Harvest  |  |
|--------|-----------|------------|------------------|------|-------|----------|--|
| rate   | mortality | (Million)  | (kt)             | (kt) | (kt)  | fraction |  |
| 100.0% | 0.000     | 6,295      | 2,014            | 505  | 0     | 0.0%     |  |
| 40.0%  | 0.263     | 6,295      | 1,186            | 202  | 225   | 19.0%    |  |
| 35.0%  | 0.311     | 6,295      | 1,113            | 177  | 245   | 22.0%    |  |

# 2024 acceptable biological catch (ABC)

The definitions of OFL and maximum permissible FABC under Amendment 56 provide a buffer between the overfishing level and the intended harvest rate, as required by NMFS national standard guidelines. Since estimates of stock biomass from assessment models are uncertain, the buffer between OFL and ABC provides a margin of safety so that assessment error will not result in the OFL being inadvertently exceeded. For GOA pollock, the maximum permissible FABC harvest rate (i.e., FABC/FOFL) is 84.7% of the OFL harvest rate. Projections for 2024 for the FOFL and the maximum permissible FABC are given in Table 1.25.

### Should the ABC be reduced below the maximum permissible ABC?

The SSC in its December 2018 minutes recommended that all assessment authors use the risk table when determining whether to recommend an ABC lower than the maximum permissible. The following template is used to complete the risk table, which was updated in 2023 to reflect only three levels of concern:

|                              | Assessment-related considerations  | Population<br>dynamics<br>considerations  | Environmental/ecosystem<br>considerations  | Fishery<br>Performance  |
|------------------------------|--|---|--|---|
| Level 1:<br>No<br>Concern    | Typical to<br>moderately increased<br>uncertainty/minor<br>unresolved issues in<br>assessment.   | Stock trends are<br>typical for the stock;<br>recent recruitment is<br>within normal range.                                     | No apparent<br>environmental/ecosystem<br>concerns   | No apparent<br>fishery/resource-use<br>performance and/or<br>behavior concerns  |
| Level 2:<br>Major<br>Concern | Major problems with<br>the stock assessment;<br>very poor fits to data;<br>high level of<br>uncertainty; strong<br>retrospective bias. | Stock trends are<br>highly unusual; very<br>rapid changes in<br>stock abundance, or<br>highly atypical<br>recruitment patterns. | Multiple indicators showing<br>consistent adverse signals a)<br>across the same trophic level as<br>the stock, and/or b) up or down<br>trophic levels (i.e., predators<br>and prey of the stock) | Multiple indicators<br>showing consistent<br>adverse signals a)<br>across different<br>sectors, and/or b)<br>different gear types |

|                                | Assessment-related considerations   | Population<br>dynamics<br>considerations  | Environmental/ecosystem<br>considerations   | Fishery<br>Performance   |
|--------------------------------|---|---|---|--|
| Level 3:<br>Extreme<br>concern | Severe problems<br>with the stock<br>assessment; severe<br>retrospective bias.<br>Assessment<br>considered<br>unreliable. | Stock trends are<br>unprecedented; More<br>rapid changes in<br>stock abundance<br>than have ever been<br>seen previously, or a<br>very long stretch of<br>poor recruitment<br>compared to<br>previous patterns. | Extreme anomalies in multiple<br>ecosystem indicators that are<br>highly likely to impact the<br>stock; Potential for cascading<br>effects on other ecosystem<br>components | Extreme anomalies<br>in multiple<br>performance<br>indicators that are<br>highly likely to<br>impact the stock |

The table is applied by evaluating the severity of four types of considerations that could be used to support a scientific recommendation to reduce the ABC from the maximum permissible. These considerations are stock assessment considerations, population dynamics considerations, environmental/ecosystem considerations, and fishery performance. Examples of the types of concerns that might be relevant include the following:

- 1. Assessment considerations—data-inputs: biased ages, skipped surveys, lack of fisheryindependent trend data; model fits: poor fits to fits to fishery or survey data, inability to simultaneously fit multiple data inputs; model performance: poor model convergence, multiple minima in the likelihood surface, parameters hitting bounds; estimation uncertainty: poorlyestimated but influential year classes; retrospective bias in biomass estimates.
- 2. Population dynamics considerations—decreasing biomass trend, poor recent recruitment, inability of the stock to rebuild, abrupt increase or decrease in stock abundance.
- 3. Environmental/ecosystem considerations—adverse trends in environmental/ecosystem indicators, ecosystem model results, decreases in ecosystem productivity, decreases in prey abundance or availability, increases or increases in predator abundance or productivity.
- 4. Fishery performance—fishery CPUE is showing a contrasting pattern from the stock biomass trend, unusual spatial pattern of fishing, changes in the percent of TAC taken, changes in the duration of fishery openings.

### Assessment considerations

Several important assessment considerations arose in 2023. The new abundance indices had conflict, with two going up and two going down. The two surveys which cover the whole extent of the Gulf were both up more than 70% from two years ago, while the two with more limited spatial coverage were down from 2022. Not surprisingly the model was not able to fit these data points, and in particular the NMFS bottom trawl index has not fit well since 2015 (Fig. 1.32).

The Shelikof abundance estimate is unexpectedly low and comprised predominantly of pollock greater than 40 cm, but also coincides with increased estimates of biomass in outlying areas, like the Chirikof shelf break and Shumagin islands, relative to recent years (Fig. 1.8). However, biomass estimates in the outlying areas are not abnormally high compared to historical surveys and the Shelikof estimate still constitutes the largest winter spawning area by far. This low Shelikof estimate is thus not well explained by spatial shifts. A mismatch between spawn timing and survey timing is another reasonable hypothesis, as the two were linked statistically via a relationship with catchability as was presented to the Groundfish Plan Team in September 2022. However, the covariate values in 2023 would suggest only moderately lower catchability and likely also not explain the poor fit to the new data point. In the end, the fit is poor but not unprecedented with this stock, and the previous few years have fit very well. We therefore believe there is no reason for a substantial concern.

In contrast, the NMFS bottom trawl survey has fit poorly for the last 5 biennial surveys (since 2015). The expected trend is the opposite of the observed trend. The consistency of this misfit is a larger concern, particularly because the prior on catchability for this index is an important contributor to estimating the scale of the stock. We therefore consider this an elevated stock assessment concern.

Finally, we highlight the poor retrospective pattern estimated this year. The estimated  $\rho = -0.308$  is considered significant, with substantial and consistent increases of estimated SSB as data are added to the model. We hypothesized that the inflexible time-varying catchability for the winter Shelikof survey, coupled with the notably low estimate in 2023, could exaggerate this retrospective pattern. To test this hypothesis we estimated the process error for the random walk (assumed to be 0.05 in the base model) to allow it increased flexibility. This type of estimation is possible because model 23.0 is in TMB. The estimated value of the process error was 0.36, a substantial increase as expected, but the retrospective pattern was actually worse and decreased to -0.40 (results not shown). It thus appears that this retrospective pattern is not driven by an inadequately flexible catchability for the Shelikof survey. Further explorations of causes and reasonable solutions to minimize this significant retrospective pattern will be done, but for now we highlight it as a stock assessment concern.

Between the poor model fits and significant retrospective pattern we assign level 2: major concerns with assessment considerations.

#### Population dynamics considerations

The large 2012 year class has had a strong impact on the recent pollock population, from a steep decline in age diversity (Fig. 1.15) to abnormal growth and maturation (but not mortality as previously suspected), which had led to an increase in concern. The estimated size of this cohort has increased substantially over the last few years, including a 9.2% and 9.9% increase in 2022 and 2023 with additional data, an increase of almost 10 billion fish from 2020 to 2023. For context, this increase alone would be considered a large cohort, and only magnifies the large impact it has on the population dynamics over the last 10 years. However, the 2012 year class, now in the 10+ age class, is no longer the predominant one in the fishery and two large ones (2017 and 2018) have already entered the fishery, with another large one in 2020 to enter in the coming years (Figs. 1.5 and 1.36), resulting in a return to normal age diversity and population dynamics.

A new phenomenon emerged in the last handful of years that is worth highlighting. Many of the estimates of recent cohort sizes are abnormally small compared to previous estimates as seen in the following figure.

These recruits have implications for  $\sigma_R$ . We used TMB's ability to estimate process errors during a retrospective peel to test how sensitive the quantity is to these cohorts (below). We found a big increase from 2015 to 2016, and again from 2022 to 2023. This demonstrates that these small cohorts have a strong influence on the perception of the variation in recruitment. A value of  $\sigma_R$  closer to 1.8 is estimated by the model using data through 2023, but  $\sigma_R = 1.3$  is assumed in the model this year. Future work will be done to further corroborate the small cohorts and explore whether recruitment variation should be updated. For now we consider 1.3 a more reasonable value.

These vanishingly small cohorts are clear aberrations and violate the statistical assumption of the assessment, namely that log-recruitment is normally distributed. They also are consistently estimated (Fig. 141) and corroborated by larval surveys. In other words, the estimates appear justified by the data. Whether this shift is caused by environmental forcing or other factors is unclear. However, from a population dynamics perspective, which considers recruitment in natural space, the effects are expected to be minimal. This is because the cohorts are not expected to contribute to the spawning stock whether they are very small or exceptionally small. It is the large cohorts that drive the population dynamics in the end. So while we highlight these abnormal recruitment failures, we do not believe it rises to the level of a major concern. We therefore give a level 1: no concern to population dynamics considerations.

### Environmental/Ecosystem considerations

Appendix 1A provides a detailed look at environmental/ecosystem considerations specific to this stock within the ecosystem and socioeconomic profile (ESP). Broad-scale information on environmental and ecosystem considerations are provided by the Gulf of Alaska Ecosystem Status Report (GOA ESR; Ferriss and Zador (2022)). The text below summarizes ecosystem information related to GOA pollock provided from both the ESP and GOA ESR.

**Environmental Processes:** The 2023 ocean temperatures are all within known optimal ranges for pollock life history stages (Feb-May 150-300m: spawning 1-7°C, Mar-Apr 0-200m: egg 5-6°C, Apr-Jul surface: larva 3-7°C, as referenced in the ESP, Appendix 1A). Western GOA temperatures at depth on the shelf were approximately average. Surface waters were approximately average/ cooler than average in the winter, spring, and fall with warmer waters in the summer (Satellite: Lemagie and Callahan (2023); Appendix 1A: Callahan, Seward Line: Danielson and Hopcroft (2023), NOAA bottom trawl: O'Leary (2023), Shelikof: Axler and Rogers (2023)). The central GOA experienced below average marine heatwave events this year, a decrease from last year (Appendix 1A: Barbeaux). The mean direction of the spring wind was southwest down Shelikof Strait suggesting retention in suitable larval habitat but sustained April offshore gap winds near Kodiak may have altered advective patterns (Appendix 1A:

Rogers). Over the western and central GOA, spring chlorophyll-a concentrations were below average and the peak spring bloom was considerably late (Satellite, Appendix 1A: Callahan). Upcoming 2024 winter and spring surface temperatures are predicted to be warmer than average, in alignment with El Niño conditions, potentially impacting larval pollock survival (depending on intensity and duration of the warming event).

**Prey**: Zooplankton biomass were below average to average on the GOA shelf in the spring and summer. Zooplankton biomass in the WGOA progressed from below average in the spring (lower small and calanoid copepod biomass and higher euphausiid biomass) to improved conditions in the summer (above average biomass of large calanoid copepods and euphausiids, but continued lower small copepod biomass; Appendix 1A: Rogers, Shelikof St., and Seward Line, Hopcroft (2023)). Summer planktivorous foraging conditions were somewhat improved with above average large calanoid copepod and euphausiid biomass, but continued lower small copepod biomass (Shelikof, Kimmel *et al.* (2023)). Planktivorous seabird reproductive success, an indicator of zooplankton availability and nutritional quality, was approximately average just south of Kodiak (Chowiet Island), and in the central GOA (Middleton Island) (Drummond *et al.* (2023), Whelan *et al.* (2023); winter acoustic survey, Appendix 1A: Monnahan). Percent euphausiids in the diet of juveniles was slightly above average (Appendix 1A: Aydin). Catches of larval and YOY pollock in spring and summer surveys were low (Shelikof St, Rogers and Porter (2023), Appendix 1A: Rogers, Kodiak beach seine survey, Appendix 1A: Laurel), suggesting less productive feeding conditions in the nearshore for larval pollock.

**Predators and Competitors**: Predation pressure from key groundfish species (arrowtooth flounder, Pacific cod, Pacific halibut, and potentially sablefish) is expected to be moderate. Pacific cod, P. halibut, and arrowtooth flounder biomass have remained relatively low (Hulson *et al.* (2023), Whorton (2023), Appendix 1A: Shotwell). The sablefish population has had multiple large age classes since 2016, potentially adding predation pressure to pollock prior to moving to adult slope habitat (sablefish assessment, Goethel *et al.* (2023), Appendix 1A). Western GOA Steller sea lions were not reassessed in 2023 but remain lower than previous biomass peaks (Sweeney and Gelatt (2023)). Potential competitors include large returns of pink salmon (Whitehouse (2023), Vulstek and Russell (2023)), a relatively large population of Pacific ocean perch (Assessment Hulson *et al.* (2022), Appendix 1A), large year classes of juvenile sablefish (Assessment, Goethel *et al.* (2023), Appendix 1A).

### Fishery performance

Trends in effort-weighted fishery CPUE were examined in the ESP (Appendix 1A) for two seasons, the pre-spawning fishery (A and B seasons) and the summer/fall fishery (C and D seasons). Fishery CPUE is either above (A and B seasons) or close to (C and D seasons) the long-term average, and is very consistent with the abundance trend of exploitable biomass from the assessment. No concerns regarding fishery performance were identified and this element was given a score of 1.

#### Summary and ABC recommendation

| Assessment-related considerations | Population dynamics considerations | Environmental/ecosystem considerations | Fishery<br>Performance |
|-----------------------------------|------------------------------------|--|------------------------|
| Level 2: Major concern            | Level 1: No concern                | Level 1: No concern                    | Level 1: No<br>concern |

Given the overall lack of elevated scores in the risk table, the author's recommended ABC is based on the maximum permissible ABC, resulting in a 2024 ABC of 232,543 t, which is a 56.1% increase from the 2023 ABC. The author's recommended 2025 ABC is 157,687 t. The OFL in 2024 is 269,916 t, and the OFL in 2025 if the 2024 ABC is taken in 2024 is 182,891 t.

To evaluate the probability that the stock will drop below the B20% threshold, we projected the stock forward for five years using the author's recommended fishing mortality schedule. This projection incorporates uncertainty in stock status, uncertainty in the estimate of B20%, and variability in future recruitment. We then sampled from the probability of future spawning biomass using Markov chain Monte Carlo (MCMC) using the no-U-turn sampler available in TMB (Monnahan and Kristensen 2018). Analysis of the posterior samples indicates that probability of the stock dropping below B20% will be negligible through 2028, conditional upon the model specified here (Fig. 1.43).

### **Projections and Status Determination**

A standard set of projections is required for each stock managed under Tiers 1, 2, or 3 of Amendment 56. This set of projections encompasses seven harvest scenarios designed to satisfy the requirements of Amendment 56, the National Environmental Policy Act, and the Magnuson-Stevens Fishery Conservation and Management Act (MSFCMA). For each scenario, the projections begin with the vector of 2023 numbers at age as estimated in the assessment. This vector is then projected forward to the beginning of 2024 using the schedules of natural mortality and selectivity described in the assessment and the best available estimate of total (year-end) catch for 2023. In each subsequent year, the fishing mortality rate is prescribed on the basis of the spawning biomass in that year and the respective harvest scenario. In each year, recruitment is drawn from an inverse Gaussian distribution whose parameters consist of maximum likelihood estimates determined from recruitments estimated in the assessment. Spawning biomass is computed in each year based on the time of peak spawning and the maturity and weight schedules described in the assessment. Total catch after 2023 is assumed to equal the catch associated with the respective harvest scenario in all years. This projection scheme is run 1,000 times to obtain distributions of possible future stock sizes, fishing mortality rates, and catches.

Five of the seven standard scenarios support the alternative harvest strategies analyzed in the Alaska Groundfish Harvest Specifications Final Environmental Impact Statement. These five scenarios, which are designed to provide a range of harvest alternatives that are likely to bracket the final TAC for 2024, are as follow (max $F_{ABC}$  refers to the maximum permissible value of  $F_{ABC}$  under Amendment 56):

- Scenario 1: In all future years, F is set equal to  $maxF_{ABC}$ . (Rationale: Historically, TAC has been constrained by ABC, so this scenario provides a likely upper limit on future TACs.)
- Scenario 2: In 2023 and 2024, *F* is set equal to a constant fraction of  $maxF_{ABC}$ , where this fraction is equal to the ratio of the realized catches in 2020- 2022 to the ABC recommended in the assessment for each of those years. For the remainder of the future years, maximum permissible ABC is used. (Rationale: In many fisheries the ABC is routinely not fully utilized, so assuming an average ratio catch to ABC will yield more realistic projections.)
- Scenario 3: In all future years, F is set equal to 50% of  $maxF_{ABC}$ . (Rationale: This scenario provides a likely lower bound on FABC that still allows future harvest rates to be adjusted downward when stocks fall below reference levels.)
- Scenario 4: In all future years, F is set equal to the 2019-2023 average F. (Rationale: For some stocks, TAC can be well below ABC, and recent average F may provide a better indicator of  $F_{TAC}$  than  $F_{ABC}$ .)
- Scenario 5: In all future years, *F* is set equal to zero. (Rationale: In extreme cases, TAC may be set at a level close to zero.)

Two other scenarios are needed to satisfy the MSFCMA's requirement to determine whether a stock is currently in an overfished condition or is approaching an overfished condition. These two scenarios are as follows (for Tier 3 stocks, the MSY level is defined as  $B_{35\%}$ ):

- Scenario 6: In all future years, F is set equal to  $F_{OFL}$ . Rationale: This scenario determines whether a stock is overfished. If the stock is expected to be 1) above its MSY level in 2023 or 2) above 1/2 of its MSY level in 2023 and above its MSY level in 2032 under this scenario, then the stock is not overfished.
- Scenario 7: In 2024 and 2025, F is set equal to max  $F_{ABC}$ , and in all subsequent years F is set equal to FOFL. Rationale: This scenario determines whether a stock is approaching an overfished condition. If the stock is 1) above its MSY level in 2025 or 2) above 1/2 of its MSY level in 2025 and expected to be above its MSY level in 2034 under this scenario, then the stock is not approaching an overfished condition.

Results from scenarios 1-7 are presented in Table 1.25. Mean spawning biomass is projected to decline to 2027 under full exploitation scenarios, but will stay stable under the F=0 and other low exploitation scenarios (Fig. 1.44). We project catches to increase through 2025, and then drop slightly in subsequent years.

Under the MSFCMA, the Secretary of Commerce is required to report on the status of each U.S. fishery with respect to overfishing. This report involves the answers to three questions: 1) Is the stock being subjected to overfishing? 2) Is the stock currently overfished? 3) Is the stock approaching an overfished condition?

The catch estimate for the most recent complete year (2022) is 132,698 t, which is less than the 2022 OFL of 173,470 t. Therefore, the stock is not subject to overfishing. The fishing mortality that would have produced a catch in 2022 equal to the 2022 OFL is 0.239.

Scenarios 6 and 7 are used to make the MSFCMA's other required status determination as follows:

Under scenario 6, spawning biomass is estimated to be 274,141 t in 2023 (see Table 1.25), which is above B35% (177,000 t). Therefore, GOA pollock is not currently overfished.

Under scenario 7, projected mean spawning biomass in 2025 is 227,091 t, which is above B35% (177,000 t). Therefore, GOA pollock is not approaching an overfished condition.

The recommended area apportionment to management areas in the central and western portions of the Gulf of Alaska (central/western/west Yakutat) are provided in Appendix 1D.

# **Data Gaps and Research Priorities**

The following research priorities were identified based on previous CIE reviews and recent Plan Team and SSC discussions:

- Explore alternative functional forms for fishery selectivity.
- Jointly estimate process errors for time-varying components like selectivity, catchability and recruitment, using integration via the Laplace approximation or MCMC.
- Consider alternative modeling platforms in parallel to the current ADMB assessment.
- Explore priors on catchability and the effect on the population scale and potentially how it relates to results from the predation mortality model.
- Revisit initial data weights for compositional data, and assumed CVs for indices.
- Estimate input variances for weight at age components in the WAA RE model.
- Continue to develop spatial GLMM models for survey indices and age composition of GOA pollock

- Evaluate pollock population dynamics in a multi-species context using the CEATTLE model.
- Explore implications of non-constant natural mortality on pollock assessment and management.

Additional recommendations that could be done by other teams at the AFSC, but are unlikely to be specifically prioritized by the primary assessment author, include:

- Efforts to combine acoustic and bottom trawl information in a vertically integrated index
- Efforts to improve understanding of changes of weight at age or and maturity at age, either via linkage to copepods/euphausiids or directly to the physical environment

# Acknowledgements

We thank the AFSC survey personnel for the collection of data, providing the biomass estimates, and discussing results, particularly Ned Laman for providing summarized data and important historical context this year. We are grateful to all the fishery observers working with the Fishery Monitoring and Analysis (FMA) Division who collect vital data for the stock assessments, and the staff of the AFSC Age and Growth Unit for the ageing of otoliths used to determine the age compositions in the assessment. We also thank Kally Spalinger for providing ADF&G survey data.

## Tables

Table 1.1. Walleye pollock catch (t) in the Gulf of Alaska. The ABC is for the area west of 140W lon. (Western, Central and West Yakutat management areas) and includes the guideline harvest level for the state-managed fishery in Prince William Sound. Catches in the current year are incomplete and excluded. Research catches are reported in Appendix 1E.

| Year | Foreign | Joint Venture | Domestic | Total            | ABC/TAC |
|------|---------|---------------|----------|------------------|---------|
| 1964 | 1.126   |               |          | 1.126            |         |
| 1965 | 2,746   |               |          | 2,746            |         |
| 1966 | 8,914   |               |          | 8,914            |         |
| 1967 | 6,272   |               |          | 6,272            |         |
| 1968 | 6,137   |               |          | 6,137            |         |
| 1969 | 17,547  |               |          | 17,547           |         |
| 1970 | 9,331   |               | 48       | 9,379            |         |
| 1971 | 9,460   |               | 0        | 9,460            |         |
| 1972 | 38,128  |               | 3        | 38,131           |         |
| 1973 | 44,966  |               | 27       | 44,993           |         |

Table 1.2. Incidental catch (t) of FMP species (upper table) and non-target species (bottom table) in the directed pollock fishery in the Gulf of Alaska. Species are in descending order according to the cumulative catch during the period. Incidental catch estimates include both retained and discarded catch.

| Species/species group            | 2018   | 2019   | 2020   | 2021   | 2022   |

Table 1.8. Survey sampling effort and biomass coefficients of variation (CV) for pollock in the NMFS bottom trawl survey. The number of measured pollock is approximate due to subsample expansions in the database. The total number measured includes both sexed and unsexed fish.

Table 1.9. Estimated number at age (millions) from the NMFS bottom trawl survey (top). Estimates are for the Western and Central Gulf of Alaska only (Management areas 610-630). Estimated number at age (millions) from the summer acoustic survey (bottom).

Table 1.19. Estimates of population biomass, recruitment, and harvest of GOA pollock from the agestructured assessment model. The harvest rate is the catch in biomass divided by the total biomass of age 3+ fish at the start of the year.

Table 1.20. Estimated selectivity at age for GOA pollock fisheries and surveys. The fisheries and surveys were modeled using double logistic selectivity functions. Acoustic survey catchablity at age 1 and age 2 are estimated separately.

| Year    | 1      | 2       | 3                   | 4     | 5         | 6        | 7   | 8        | 9      | 10                   |

Table 1.22. Uncertainty of estimates of recruitment and spawning biomass of GOA pollock from the agestructured assessment model.

Table 1.23. GOA pollock life history and fishery characteristics used to estimate spawning biomass per recruit (FSPR) harvest rates. Spawning weight at age (WAA, kg) is based on an average from the Shelikof Strait acoustic survey conducted in March. Population weight at age is based on a average for the last three bottom trawl survey conducted in June to August. Proportion mature females is the average from winter acoustic survey specimen data.

| Age | Natural<br>mortality | Fishery<br>selectivity<br>(Avg. 2019-<br>2023) | Spawning<br>WAA<br>(Avg. 2019-<br>2023) | Population WAA<br>(Avg. 2017, 2019,<br>2021) | Fishery WAA<br>(Est. 2023 from<br>RE model) | Proportion mature<br>females<br>(Avg. 1983-2023) |

Table 1.24. Methods used to assess GOA pollock. The basis for catch recommendation in 1977-1989 is the presumptive method by which the ABC was determined (based on the assessment and SSC minutes). The basis for catch recommendation given after 1989 is the method used by the Plan Team to derive the ABC recommendation given in the SAFE summary chapter.

| Year        | Assessment Method  | Catch recommendation basis   | B40%<br>(t) |

Table 1.25. Projections of GOA pollock spawning biomass, full recruitment fishing mortality, and catch for 2023 - 2036 under different harvest policies (columns). For these projections, fishery weight at age was assumed to be equal to the estimated weight at age in 2023 for the RE model. All projections begin with initial age composition in 2023 using the base run model with a projected 2023 catch of 145,215 t. The values for B100%, B40%, and B35% are 505,000 t, 202,000 t, 177,000 t, respectively

| Spawning biomass (t) |           |               |           |                  |                 |           |                  |

Appendix 1.A is available at this external link: https://appsafsc.fisheries.noaa.gov/Plan Team/2023/GOApollock appA.pdf

### Appendix 1B. Southeast Alaska pollock assessment

Bottom trawl surveys indicate a substantial reduction in pollock abundance east of 140° W. lon. Stock structure in this area is poorly understood. Bailey et al. (1999) suggest that pollock metapopulation structure in southeast Alaska is characterized by numerous fiord populations. In the 2023 NMFS bottom trawl survey, higher pollock CPUE in southeast Alaska occurred primarily from Baranof Island south to Dixon Entrance, where the shelf is broader. Pollock length composition in the 2023 bottom trawl survey showed a dominant mode at 20 cm about from 30 to 60 cm (Fig. A.1). Juveniles in this area are unlikely to influence the population dynamics of pollock in the central and western Gulf of Alaska. Ocean currents are generally northward in this area, suggesting that juvenile settlement is a result of spawning further south. Spawning aggregations of pollock have been reported from the northern part of Dixon Entrance (Saunders et al. 1988).

Historically, there has been little directed fishing for pollock in Southeast Alaska (Fritz 1993). Pollock catch in the Southeast and East Yakutat statistical areas has averaged about 2 t since 2012 (Table 1.4). The ban on trawling east of 140° W. lon. prevents the development of a trawl fishery for pollock in Southeast Alaska, though recently there has been interest in directed pollock fishing using other gear types, such as purse seine.

Biomass in Southeast Alaska was estimated by splitting survey strata and CPUE data in the Yakutat statistical area at 140° W. lon. and combining the strata east of the line with comparable strata in the Southeastern statistical area. Surveys since 1996 had the most complete coverage of shallow strata in southeast Alaska, and indicate that stock size is approximately 25-75,000 t (Appendix Fig. B.1). There is a gradual increase in biomass since 2005, but confidence intervals are large. A random effects model was fit to the 1990-2023 bottom trawl survey biomass estimates in southeast Alaska. We recommend placing southeast Alaska pollock in Tier 5 of the NPFMC tier system, and basing the ABC and OFL on natural mortality (0.3) and the biomass estimate from the random effects model (43,328 t). The new model estimate results in a 2024 ABC of 9,749 t (43,328 t \* 0.75 M), and a 2024 OFL of 12,998 t (43,328 t \* M). The same ABC and OFL are recommended for 2025.

Appendix figure 1B.1. Pollock length composition in 2023 (left) and biomass trend in southeast Alaska from a random effects model fit to NMFS bottom trawl surveys in 1990-2023 (right). Error bars indicate plus and minus two standard deviations. The solid line is the biomass trend from the random effects model, while dotted lines indicate the 95% confidence interval.

### Appendix 1C. GOA pollock stock assessment model

### **Population dynamics**

The age-structured model for pollock describes the relationships between population numbers by age and year. The modeled population includes individuals from age 1 to age 10, with age 10 defined as a "plus" group, i.e., all individuals age 10 and older. The Baranov (1918) catch equations are assumed, so that

$$c_{ij} = N_{ij} \frac{F_{ij}}{Z_{ij}} [I - \exp(-Z_{ij})]$$
$$Z_{ij} = \sum_{k} F_{ij} + M_{j}$$
$$N_{i+lj+l} = N_{ij} \exp(-Z_{ij})$$

except for the plus group, where

$$N_{i+1,10} = N_{i,9} \exp(-Z_{i,9}) + N_{i,10} \exp(-Z_{i,10})$$

where  $N_{ij}$  is the population abundance at the start of year *i* for age *j* fish,  $F_{ij}$  = fishing mortality rate in year *i* for age *j* fish, and  $C_{ij}$  = catch in year *i* for age *j* fish. The natural mortality rate,  $M_j$ , is age-specific, but does not vary by year (at least for now).

Fishing mortality is modeled as a product of year-specific and age-specific factors (Doubleday 1976)

$$F_{ij} = s_j f_i$$

where  $s_j$  is age-specific selectivity, and  $f_i$  is the annual fishing mortality rate. To ensure that the selectivities are well determined, we require that max  $(s_j) = l$ . Following previous assessments, a scaled double-logistic function (Dorn and Methot 1990) was used to model age-specific selectivity,

$$s'_{j} = \left(\frac{l}{l + \exp\left[-\beta_{1}(j - \alpha_{1})\right]}\right) \left(l - \frac{l}{l + \exp\left[-\beta_{2}(j - \alpha_{2})\right]}\right)$$

$$s_j = s'_j / \max(s'_j)$$

where  $\alpha_1$  = inflection age,  $\beta_1$  = slope at the inflection age for the ascending logistic part of the equation, and  $\alpha_2$ ,  $\beta_2$  = the inflection age and slope for the descending logistic part.

### **Measurement error**

Model parameters were estimated by maximum likelihood (Fournier and Archibald 1982, Kimura 1989, 1990, 1991). Fishery observations consist of the total annual catch in tons,  $C_i$ , and the proportions at age in the catch,  $p_{ij}$ . Predicted values from the model are obtained from

$$\hat{C}_i = \sum_j w_{ij} c_{ij}$$

$$\hat{p}_{ij} = c_{ij} / \sum_{j} c_{ij}$$

where  $W_{ij}$  is the weight at age j in year i. Year-specific weights at age are used when available.

Log-normal measurement error in total catch and multinomial sampling error in the proportions at age give a log-likelihood of

$$\log L_{k} = -\sum_{i} \left[ \log (C_{i}) - \log (\hat{C}_{i}) \right]^{2} / 2 \sigma_{i}^{2} + \sum_{i} m_{i} \sum_{j} p_{ij} \log (\hat{p}_{ij} / p_{ij})$$

where  $\sigma_i$  is standard deviation of the logarithm of total catch (~ CV of total catch) and  $m_i$  is the size of the age sample. In the multinomial part of the likelihood, the expected proportions at age have been divided by the observed proportion at age, so that a perfect fit to the data for a year gives a log likelihood value of zero (Fournier and Archibald 1982). This formulation of the likelihood allows considerable flexibility to give different weights (i.e. emphasis) to each estimate of annual catch and age composition. Expressing these weights explicitly as CVs (for the total catch estimates), and sample sizes (for the proportions at age) assists in making reasonable assumptions about appropriate weights for estimates whose variances are not routinely calculated.

Survey observations consist of a total biomass estimate,  $B_i$ , and survey proportions at age  $\pi_{ij}$ . Predicted values from the model are obtained from

$$\hat{B}_i = q \sum_{j} W_{ij} S_j N_{ij} \exp\left[\phi_i Z_{ij}\right]$$

where q = survey catchability,  $w_{ij}$  is the survey weight at age *j* in year *i* (if available),  $s_j$  = selectivity at age for the survey, and  $\phi_i$  = fraction of the year to the mid-point of the survey. Although there are multiple surveys for GOA pollock, a subscript to index a particular survey has been suppressed in the above and subsequent equations in the interest of clarity. Survey selectivity was modeled using either a double-logistic function of the same form used for fishery selectivity, or simpler variant, such as single logistic function. The expected proportions at age in the survey in the *i*th year are given by

$$\hat{\pi}_{ij} = s_j N_{ij} \exp[\phi_i Z_{ij}] / \sum_j s_j N_{ij} \exp[\phi_i Z_{ij}]$$

Log-normal errors in total biomass and multinomial sampling error in the proportions at age give a log-likelihood for survey k of

$$\log L_{k} = -\sum_{i} \left[ \log (B_{i}) - \log(\hat{B}_{i}) + \sigma^{2}/2 \right]^{2} / 2 \sigma_{i}^{2} + \sum_{i} m_{i} \sum_{j} \pi_{ij} \log(\hat{\pi}_{ij} / \pi_{ij})$$

where  $\sigma_i$  is the standard deviation of the logarithm of total biomass (~ CV of the total biomass) and  $m_i$  is the size of the age sample from the survey.

### **Process error**

Process error refers to random changes in parameter values from one year to the next. Annual variation in recruitment and fishing mortality can be considered types of process error (Schnute and Richards 1995). In the pollock model, these annual recruitment and fishing mortality parameters are generally estimated as free parameters, with no additional error constraints. We use process error to describe changes in fisheries selectivity over time. To model temporal variation in a parameter  $\gamma$ , the year-specific value of the parameter is given by

$$\gamma_i = \overline{\gamma} + \delta_i$$

where  $\overline{\gamma}$  is the mean value (on either a log scale or an arithmetic scale), and  $\delta_i$  is an annual deviation subject to the constraint  $\sum \delta_i = 0$ . For a random walk where annual *changes* are normally distributed, the log-likelihood is

$$\log L_{Proc. Err.} = -\sum \frac{\left(\delta_i - \delta_{i+1}\right)^2}{2\sigma_i^2}$$

where  $\sigma_i$  is the standard deviation of the annual change in the parameter. We use a process error model for the two parameters for the ascending portion of the fishery double-logistic curve. Variation in the intercept selectivity parameter is modeled using a random walk on an arithmetic scale, while variation in the slope parameter is modeled using a log-scale random walk. We also use a process error model for catchability for the Shelikof Strait acoustic survey and the ADFG bottom trawl survey to account for changes in the proportion of the stock surveyed.

The total log likelihood is the sum of the likelihood components for each fishery and survey, plus a term for process error,

$$\operatorname{Log} L = \sum_{k} \operatorname{Log} L_{k} + \sum_{p} \operatorname{Log} L_{Proc. Err.}.$$

# Appendix 1D. Seasonal distribution and apportionment of pollock among management areas in the Gulf of Alaska

Since 1992, the GOA pollock TAC has been apportioned between management areas based on the distribution of biomass in groundfish surveys. Steller sea lion protection measures that were implemented in 2001 require apportionment of pollock TAC based on the seasonal distribution of biomass. Both single species and ecosystem considerations provide rationale for apportioning the TAC. From an ecosystem perspective, apportioning the TAC will spatially distribute the effects of fishing on other pollock consumers, such as Steller sea lions, potentially reducing the overall intensity of any adverse effects. Apportioning the TAC also ensures that no smaller component of the stock experiences higher mortality than any other. Although sub-stock units of pollock have not been identified in the Gulf of Alaska, managing the fishery so as to preserve the existing spatial structure could be regarded as a precautionary approach. Protection of sub-stock units would be most important during spawning season, when they would be separated spatially.

Recently NMFS approved the final rule for Amendment 109 to GOA Fishery Management Plan developed by the North Pacific Fisheries Management Council. Amendment 109 combines pollock fishery A and B seasons into a single season (redesignated as the A season), and the C and D seasons into a single season (redesignated as the B season), and changes the annual start date of the redesignated pollock B season from August 25 to September 1. The TAC is still allocated 50% to a pre-spawning season (new A season) and 50% to a late summer season (new B season). These changes will be implemented beginning in 2021 and affect the seasonal allocation only in the Central and Western GOA. Our approach to implementing this regulation change is to use the same methodology as was used previously to apportion the TAC into the A, B, C, and D seasons, and then to aggregate the A and B season allocations into the new B season. This approach ensures that there is no net redistribution between management areas due to the new season structure.

Pollock in the GOA undergo an annual migration between summer foraging habitats and winter spawning grounds. Since surveying effort has been concentrated during the summer months, and prior to spawning in late winter, the dynamics and timing of this migration are not well understood. Regional biomass estimates are highly variable, indicating either large sampling variability, large interannual changes in distribution, or, more likely, both. There is a comprehensive survey of the Gulf of Alaska in summer, but surveying during winter has historically focused on the Shelikof Strait spawning grounds. Recently there has been expanded acoustic surveying effort outside of Shelikof Strait in winter, but there have been only infrequent attempts to survey all or most of the known spawning areas in GOA.

### Winter apportionment

An annual acoustic survey on pre-spawning aggregations in Shelikof Strait has been conducted since 1981. Since 2000, additional spawning areas have been surveyed multiple times, including Sanak Gully, the Shumagin Islands, the shelf break near Chirikof Island, and Marmot Bay. Although none of these spawning grounds are as important as Shelikof Strait, especially from a historical perspective, in some years the aggregate biomass surveyed outside Shelikof Strait has been comparable to that within Shelikof Strait.

As in previous assessments, a "composite" approach was used to estimate the percent of the total stock in each management area. The estimated 2+ biomass for each survey was divided by the total 2+ biomass of pollock estimated by the assessment model in that year and then split into management areas for surveys that crossed management boundaries. The percent for each survey was added together to form a composite biomass distribution, which was then rescaled so that it summed to 100%. Model estimates of

2+ biomass at spawning took into account the total mortality between the start of the year and spawning, and used mean weight at age from Shelikof Strait surveys.

We used the four most recent surveys at each spawning area, and used a rule that a minimum of three surveys was necessary to include an area. This criterion is intended to provide estimates that reflect recent biomass distribution while at the same time providing some stability in the estimates. The biomass in these secondary spawning areas tends to be highly variable from one year to the next. Areas meeting this criterion were Shelikof Strait, the shelf break near Chirikof Island, the Shumagin area, Sanak Gully, Morzhovoi Bay, Pavlof Bay, and Marmot Bay. While the spawning aggregations found in the Kenai Bays, and in Prince William Sound are likely important, additional surveys are needed to confirm stability of spawning in these areas before including them in the apportionment calculations. There are also several potentially difficult issues that would need to dealt with, for example, whether including biomass in the Kenai Bays would lead increased harvests on the east side of Kodiak, both of which are in area 630. In addition, the fishery inside Prince William Sound (area 649) is managed by the State of Alaska, and state management objectives for Prince William Sound would need to be considered.

The sum of the percent biomass for all surveys combined was 40.79% which may reflect sampling variability, or interannual variation in spawning location. After rescaling, the resulting average biomass distribution was 6.01%, 87.07%, and 6.92% in areas 610, 620, and 630 (Appendix table 1D.1). In comparison to last year, the percentage in area 610 is 3.6 percentage points higher, -4.7 percentage points lower in area 620, and 1.2 percentage points higher in area 630.

### A1-season apportionment between areas 620 and 630

In 2002, based on evaluation of fishing patterns which suggested that the migration to spawning areas was not complete by January 20, the Gulf of Alaska plan team recommended an alternative apportionment scheme for areas 620 and 630 based on the average of the summer and winter distributions in area 630. This approach was not used for area 610 because fishing patterns during the A1 season suggested that most of the fish captured in area 610 would eventually spawn in area 610. The resulting A1 season apportionment is: 610, 6.0%; 620, 70.2%; 630, 23.8%. Under the new season structure, 25% of the TAC allocated in this way, and 25% is allocated based on the winter survey-estimated distribution in the previous section to comprise the new A season allocation.

### Summer distribution

Several allocation options were presented to the plan team in 2017 to account for the variability and lack of consistency in the bottom trawl and the acoustic surveys. The option that was recommended and adopted by the plan team was a 3-survey weighted average of the sum of the acoustic and bottom trawl biomass estimates for each area. The weighted average gave weights of 1.0, 0.5, and 0.25 to 2017, 2015, and 2013, respectively. Updating this approach using 2021, 2019, and 2017 surveys gave the resulting apportionment is 610, 36.0%; 620, 21.5%; 630, 39.5%; 640, 3.0%.

### Apportionment for area 640

The apportionment for area 640, which is not managed by season, is based on the estimated summer distribution of the biomass. The percentage (3.0%) of the TAC in area 640 is subtracted from the TAC before allocating the remaining TAC by season and region. The overall allocation by season and area is given in Appendix table 1D.2.

3) Calculate seasonal apportionments of ABC for the A1, A2, B1, and B2 seasons for areas 610-630

| ABC(t)          | Percent | ABC(t)  |
|-----------------|---------|---------|
| A1 season       | 25%     | 54,986  |
| A2 season       | 25%     | 54,986  |
| B1 & B2 seasons | 50%     | 109,972 |

4) For the A1 season, the ABC allocation in 630 is based on an average of winter and summer distributions. For the A2 season, the allocation of ABC is based on the winter biomass distribution.

|      |     | A1 season |        | A2 sea  | son    |
|------|-----|-----------|--------|---------|--------|
| Area |     | Percent   | ABC(t) | Percent | ABC(t) |
|      | 610 | 6.0%      | 3,305  | 6.0%    | 3,305  |
|      | 620 | 70.2%     | 38,585 | 87.1%   | 47,876 |
|      | 630 | 23.8%     | 13,096 | 6.9%    | 3,805  |

5) For the B1 and B2 seasons, the allocation is based on the summer biomass distribution.

|      |     | B1 & B2 season |        |  |
|------|-----|----------------|--------|--|
| Area |     | Percent        | ABC(t) |  |
|      | 610 | 37.1%          | 40,793 |  |
|      | 620 | 22.2%          | 24,406 |  |
|      | 630 | 40.7%          | 44,773 |  |

6) For the A and B seasons, add A1 and A2, and B1 and B2. Area 640 catch is not portioned by season.

|      | AE       | ABC(t)   |          | Percent  |  |
|------|----------|----------|----------|----------|--|
| Area | Season A | Season B | Season A | Season B |  |
| 610  | 6,611    | 40,793   | 2.9%     | 18.0%    |  |
| 620  | 86,461   | 24,405   | 38.1%    | 10.8%    |  |
| 630  | 16,901   | 44,773   | 7.5%     | 19.7%    |  |
| 640  | 6,785    |          | 3.0      | %        |  |

## Appendix 1E. Supplemental catch data

To comply with the Annual Catch Limit (ACL) requirements, estimates have been developed by the Alaska for non-commercial catches and removals from NMFS-managed stocks in Alaska. (Appendix table 1E.1). Reported non-commercial catches primarily include catches associated with surveys and research projects. Small amounts of pollock catch are attributed to subsistence and bait for crab. It is important to note that there is unreported incidental catch of pollock in other fisheries in Alaska, such as the salmon fishery, which, based on anecdotal reports, may be substantial on occasion.

Appendix table 1E.1. Non-commercial catch (t) of pollock in the GOA by collection agency.

| Year |      | ADF&G  | IPHC | NMFS    |

# Appendix 1F: Exploring non-parametric and semi-parametric selectivity using 2d and 3d AR(1) smoothers

Grant D. Adams and Cole C. Monnahan

2023 - 10 - 17

### **Executive Summary**

Fishery age composition residuals have suggested misfit for this model for several decades, and has been a point of concern for the PT and SSC. More flexible configurations for fishery selectivity need to be explored. Facilitation of a new suite of more flexible non-parametric and semi-parametric selectivities in a more rigorous statistical framework requires moving away from ADMB and toward its replacement TMB. We thus ported model 19.1a (the 2022 final model) to TMB and demonstrate nearly identical estimates. We call the TMB version of 19.1a model 23.0 to reflect the change in software framework. We then used model 23.0 to explore a suite of fisheries selectivities which vary in their flexibility and where that flexibility is permitted. We conclude that two non-parametric models would make for an improved fisheries selectivity formulation based on analyzing OSA residuals, AIC model selection, and reduction in retrospective bias. The models are 23.0a which uses a 2D AR(1) model, and 23.0b which uses a so-called 3D AR(1) process that parses age, year, and cohort correlations from the data. These models are not expected to greatly impact management advice, but we believe their improved performance and projection capabilities make for a better stock assessment moving forward.

# Proposed models

#### Model 23.0: Bridging from ADMB to Template Model Builder

Template Model Builder [TMB; Kristensen et al. (2016)] is a software platform designed to estimate complex, non-linear hierarchical models. Its primary feature is the ability to efficiently apply the Laplace approximation to the marginal likelihood, so that process errors can be estimated using standard numerical optimization (Skaug and Fournier 2006). It is widely seen as the successor to ADMB, which has limited Laplace approximation capabilities and thus a penalized maximum likelihood approach is generally taken (i.e., process errors fixed and random effects estimated as fixed effects). Despite this important advantage, there have been relatively few implementations for stock assessments in the North Pacific. TMB is used more widely in other areas, such as WHAM (Stock and Miller 2021) on the US East Coast, and SAM (Nielsen and Berg 2014) in Europe. A WHAM version of the GOA pollock assessment was presented to the Plan Team in 2022, but there are advantages to using a bespoke model like the ADMB version developed by Martin Dorn and used for decades. Here we present a direct port of the 2022 accepted ADMB model 19.1a to TMB. Due to a change in software we name this model 23.0, although our initial goal is to match model 19.1a as close as possible.

We therefore converted the bespoke ADMB model to TMB. There are a few important differences between ADMB and TMB in terms of syntax and functionality relevant to stock assessments. TMB has no native phased estimation capabilities (although there is an R function that serves a similar purpose) so all parameters

are estimated simultaneously starting from their initial values. We used the 19.1a MLE estimates as initial values in model 23 and were able to obtain the same model predictions, and when optimized from there the same standard errors (uncertainties) for parameters and derived quantities (Fig. 1). TMB does not have an equivalent to ADMB's "dev\_vector" parameter class which penalizes a vector to have a mean of zero. Model 19.1a uses this feature by estimating a single mean in addition to the vector. When converting to a standard unpenalized vector, a degree of freedom is lost. The means are thus fixed at arbitrary values and mathematically the two become equivalent.

Figure 1: Results of bridging the ADMB 19.1a model to TMB model 23.0. Shown are estimates and standard errors (SE) for two key outputs, annual recruitment (in billions) and spawning stock biomass (SSB; in M t). The differences, calculated as (TMB-ADMB)/ADMB are very small, typically less than 0.02%, and presumably due to differences in the optimizer and precision of data inputs.

#### Non-parametric and semi-parametric fisheries selectivity

This stock has had persistent residual patterns in the fishery age composition data for many years, particularly for age 4 and 5 (Fig. 2). This has been a concern of the PT for many years. For instance

The GOA Plan Team in its November 2019 minutes recommended the author examine fishery selectivity, as persistent patterns in the catch-at-age residuals may represent artifacts of the selectivity functional form used.

In 2022 several ad hoc approaches were explored which demonstrated that a more flexible fisheries selectivity form could reduce the residual patterns. However, these approaches were difficult to justify and relied on arbitrarily setting likelihood penalties of time-varying selectivity curves. Instead it would be ideal to explore more flexible selectivity options based on published literature, and estimate the amount of flexibility from the data. We therefore use model 23.0 to explore alternative selectivity parameterizations. First, we review three important classes of hierarchical modeling approaches that can be used for selectivity: parametric, non-parametric, and semi-parametric functions.

Figure 2: OSA residuals (leaving out age 1) for the 2022 accepted model. Persistent patterns in age 4, 5, and 9 fish have been a point of concern.

#### Parametric models

Parametric selectivity curves are mathematical functions that have typically 2-4 parameters that define a specific form or shape (often asymptotic or dome shaped). Some common functions selected for parametric selectivity are: double normal, logistic, and double logistic. The pollock model has used double logistic historically. They are usually selected based on hypothesized interactions between fishing/survey gear and the stock. That interaction accounts for "availability (i.e., the probability that a fish of a specific age or size is in the same vicinity at the same time as gear deployment) and contact (or gear) selectivity (i.e., the relative probability that a fish of specific age or size is caught given it is available to the gear" (Privitera-Johnson, Methot, and Punt 2022).

A common way to incorporate time variation in parametric models is to let the parameters vary over time, penalized as a random walk or AR(1) process. This is the current situation for model 19.1a, and historical models, where the ascending inflection point and slope parameters are time-varying. Arbitrary penalties are used in a penalized maximum likelihood context. With TMB, the variances are now estimable.

#### Non-parametric models

Non-parametric selectivity functions are functions that estimate parameters for each age or age by year to flexibly estimate the shape based on available data. Non-parametric models penalize large fluctuations between ages and/or years because it is unlikely that the availability or contact selectivity has large shifts between ages and/or years. For example, the Woods Hole Assessment Model (WHAM) can estimate agespecific parameters with additional yearly variation penalized by a year and age 2D-AR1 function (Stock and Miller 2021). Similarly, the stock assessment model (SAM) can estimate year and age specific selectivity that follows a random walk with multivariate normal increments that can include multiple correlation parameterizations (Nielsen and Berg 2014).

Recently Cheng et al. (2023) introduced a computationally efficient form of the 2D AR(1) process that parses variation by age, year and cohort. They provide a "marginal variance" and "conditional variance" version of this approach, which differ in how the covariance matrix is calculated. A priori the marginal variance option

seems a better fit, but both are explored. The main potential advantage of this "3D" approach over the 2D one is that if there is cohort targeting by the fishery then this signal could be detected and propagated into projected selectivity, thus improving near-term estimates of SPR and management reference points.

In our non-parametric models, we estimate a mean selectivity at each age (ages 1-10), with deviations around those means allowing for flexibility. These deviations can be configured to correlate by age, year, or age and year (2D), or age, year and cohort (3D). The variances and correlations associated with these AR(1) models are estimable by TMB simultaneously with the rest of the assessment, hence uncertainty is appropriately propagated through the model.

#### Semi-parametric models

Semi-parametric selectivity functions are an intermediate between non-parametric and parametric models. The key difference is that a constant parametric form is estimated, and then the predicted selectivity at each age is scaled based on an exponentiated random effect deviation. Xu et al. (2019) develop a semi-parametric curve that combines the parametric logistic function with 2D-AR1 age and year specific nonparametric deviations. We extend this approach for the double logistic used for pollock. The configuration and estimation of the non-parametric component is the same.

### Model set explored

Since model 23 is in TMB it is now possible to explore a large suite of new flexible selectivity forms. We wanted to explore how internally estimating time-varying fisheries selectivity would behave and compare to model 19.1a generally, so we selected a fairly large set of models (Table 1).

The selectivity equation details are given below.

• Mod 0: Parametric double logistic

$$-Sel_{age} = f_1(age)$$

$$- f_1(age) = 1/(1 + exp(-slp_1 * (age - inf_1)) * (1 - 1/(1 + exp(-slp_2 * (age - inf_2))))$$

- Mod 1: Parametric double logistic w/ random effects on ascending parameters
  - $Sel_{(age,y)} = f_1(age)$  as above but:

$$- slp_{1,y} = slpdev_{1,y}$$

$$-inf_{1,y} = inf_d ev_{1,y}$$

$$- slpdev_{1,u} - slpdev_{1,u-1} \sim N(0,\sigma)$$

- $slpdev_{1,y} slpdev_{1,y-1} \sim N(0,\sigma)$  $infdev_{1,y} infdev_{1,y-1} \sim N(0,4*\sigma)$
- Mod 2: Semi-parametric double logistic \* AR(1) by age
  - $-Sel_{age} = f_1(age) * exp(dev_{age})$

$$- dev_{age} \sim MVN(0, \Sigma_a)$$

- Mod 3: Semi-parametric double logistic \* AR(1) by year
  - $Sel_{age,y} = f_1(age) * exp(dev_y)$  $dev_y \sim MVN(0, \Sigma_y)$
- Mod 4: Semi-parametric double logistic \* 2D-AR(1) by age, year

$$- Sel_{age,y} = f_1(age) * exp(dev_{age,y}) \\ - dev_{age,y} \sim MVN(0, \Sigma_{age,y})$$

• Mod 5: Non-parametric by age

$$-Sel_{age} = f_2(age)$$
  
-  $f_2(age) = 1/(1 + exp(-(par_{age})))$ 

• Mod 6: Non-parametric AR(1) by year

$$- Sel_{age,y} = 1/(1 + exp(-(selpar_{age} + dev_y)) - dev_y \sim MVN(0, \Sigma_y)$$

• Mod 7: Non-parametric 2D AR(1) age, year

$$- Sel_{age,y} = 1/(1 + exp(-(selpar_{age} + dev_{age,y}))) - dev_{age,y} \sim MVN(0, \Sigma_{age,y})$$

• Mod 8: 3D AR(1) by a, y, and cohort using conditional variance

$$- Sel_{age,y} = 1/(1 + exp(-(selpar_{age} + dev_{age,y}))) - dev_{age,y} \sim MVN(0, \Sigma_{age,cohort,y})$$

- Mod 9: 3D AR(1) by a, y, and cohort using marginal variance

$$- Sel_{age,y} = 1/(1 + exp(-(selpar_{age} + dev_{age,y}))) - dev_{age,y} \sim MVN(0, \Sigma_{age,cohort,y})$$

where  $selpar_{age}$  are age-specific parameters for the non-parametric selectivity curve,  $dev_{age,y}$  are the random deviates for the non-parametric selectivity that are multivariate normal with covariance  $\Sigma$ .

Table 1: Fisheries selectivity models considered and fit.

#### Selecting and validating flexible selectivity forms

Below we fit the alternative selectivity options (Table 1) to explore model behavior and help understand the level of complexity and flexibility needed to appropriately model fisheries selectivity. We use three primary tools to compare and contrast these models. First, we use one-step-ahead (OSA) residuals which are an improved tool over the ubiquitous Pearson residuals (Trijoulet et al. 2023). These residuals are expected to be standard normal under a correctly-specified model. We focus on visual inspection via bubble plots for non-random patterns by age, year, or cohort, as is common for Pearson residuals, instead of relying on statistical tests of normality or other properties. In particular for this example we focus on residuals for ages 3-5 which have been identified as problematic previously.

Second, we use marginal AIC for model selection. Model selection is not routinely used for stock assessment models because of the challenges associated with interpreting selection criteria when fitting to different types of data whose weights are often tuned and the use of penalized maximum likelihood (Maunder and Punt 2013; Punt, Hurtado-Ferro, and Whitten 2014). An added complication with the hierarchical models investigated here is that the penalty for the number of effective parameters does not include the random effects. Conditional AIC accounts for this but is not available at the moment. So, while the interpretation of differences in AIC is not as straightforward as in other statistical contexts, AIC still provides some important insight into the performance of the different models examined here.

Finally, we are interested in the retrospective stability and ability of the model to estimate selectivity in the current year and near-term projections when no age data are available to inform selectivity. In previous models a 4-year average prior to the terminal year of the assessment was used, but this ignores signals of annual and cohort trends in the data. We compare these approaches using retrospective projections of age-specific selectivity and spawning stock biomass for each model. Specifically, consecutive years of data were removed, the model was refit, selectivity was projected forward one year. Projected age-specific selectivity in year y from a model fit using data until year y - 1 was compared to estimated age-specific selectivity in year y from a model fit using data until year y using average relative error and mean squared error:

$$RE_{age} = \sum_{p}^{N_{p}} \left( Sel_{M(y-p),age,y-p+1} - Sel_{M(y),age,y-p+1} \right) / Sel_{M(y),age,y-p+1} / N_{p}$$
$$MSE_{age} = \sum_{p}^{N_{p}} \left( Sel_{M(y-p),age,y-p+1} - Sel_{M(y),age,y-p+1} \right)^{2} / N_{p}$$

where  $RE_{age}$  and  $MSE_{age}$  are the relative error and mean squared error, respectively, for projected selectivity-at-age (Table 1),  $Sel_{M(y-p),age,y-p+1}$  is the one-year projected selectivity from a model fit using data until year y - p (M(y-p)),  $Sel_{M(y),age,y-p+1}$  is the estimated selectivity from model fit using all available data until year y (M(y)),and  $N_p$  is the number of retrospective peels ( $N_p = 7$ ). Note, that Francis weights were not updated for each retrospective peel. The above metrics were also calculated where projected selectivity  $Sel_{M(y-p),age,y-p+1}$  was replaced with the average age-specific selectivity from the last five years, as is currently done for setting reference points.  $RE_{age}$  is referred to as Mohn's Rho.

Mohn's Rho was calculated for spawning stock biomass and mean recruitment (1978 to last year of the assessment -1) across peels for each model. Additionally, Mohn's Rho and MSE was calculated for the following biological reference points (BRPs): SB0, SB40, OFL, and ABC:

$$RE_{BRP} = \sum_{p}^{N_{p}} \left( BRP \left[ Sel_{M(y-p)}, Wt_{y-p} \right] - BRP \left[ Sel_{M(y)}, Wt_{y-p} \right] \right) / BRP \left[ Sel_{M(y)}, Wt_{y-p} \right] / N_{p}$$
$$MSE_{BRP} = \sum_{p}^{N_{p}} \left( BRP \left[ Sel_{M(y-p)}, Wt_{y-p} \right] - BRP \left[ Sel_{M(y)}, Wt_{y-p} \right] \right)^{2} / N_{p}$$

Table 2: Comparison of selectivity models for the 2022 assessment model. Models selected for comparison are highlighted in grey. NLL=negative log likelihood, Fsh = fishery age composition; K=number of fixed effects; dAIC=delta AIC.

| Model           | Total NLL | Fsh NLL | Κ   | dAIC  | 2023 SSB    | B0          | B40         | 2023  OFL   | 2023 ABC    |

-where  $RE_{BRP}$  and  $MSE_{BRP}$  are the relative error and mean squared error, respectively, for each BRP calculated using the either the one-year projected selectivity from a model fit using data until year y - p (M(y-p)),  $Sel_{M(y),age}$  or estimated selectivity from model fit using all available data until year y (Note, projection year and age is removed for simplicity). Weight-at-age  $(Wt_{y-p})$ , recruitment, and other biological parameters used for BRP calculation were extracted prior to year y - p for both models, thus representing dynamic reference points in the case of the model fit using all available data. The above metrics were also calculated where projected selectivity  $Sel_{M(y-p)}$  was replaced with the average age-specific selectivity from the last five years, as is currently done for setting reference points.

# Results

### Model fits

Many models listed in Table 1 had poor performance (discussed more below) or do not have substantial flexibility to address the initial problem (Table 2). Additionally, model 9: 3D-AR1 with marginal variance did not converge. These models are ignored for clarity, and we focus on what we consider the most promising two new models: 2D-AR1 and 3D-AR1cond, and include ParDev (which is similar to accepted model 19.1a), and the Constant model as a baseline. Model 8: 3D-AR1 with conditional variance resulted in the lowest AIC followed by model 1: ParDevs (Table 2).

The estimated AR(1) parameters for the 2D-AR1 model are 0.869 (95% CI of 0.738-0.937) for the correlation by age and 0.628 (0.339-0.809) for the correlation by year, both positive and strongly statistically significant. The estimated process error was 0.259 (0.175-0.384). For the 3D-AR1 model the estimated **partial** correlations were 0.71 (0.566-0.868) for age, -0.076 (-0.597-0.455) for year, and 0.400 (-0.254-1.053) for cohort. Thus, the year correlation is not significant, the cohort one positive but not significant, and the age correlation highly significant. Finally, the estimated process error for the 3D-AR1 model was 0.277 (0.197-0.389) which was similar in magnitude and uncertainty as in the 2D model.

Spawning stock biomass (SSB) was relatively similar among the new TMB models, particularly in later years (Fig. 3) with a projected SSB of between 212 and 226 kt in 2023 (Table 2). However, the TMB models all had a higher 2023 SSB than 19.1a (Table 2) and lower uncertainty (Fig. 3). It is unclear why this is but is likely a configuration issue that can be resolved with more time. The TMB models differ in their calculation of ABC because rather than use the average fishery selectivity from the last five years of the assessment, they use predicted selectivity in 2023.

The estimated annual selectivity at age also had the same general patterns, but with some important differences. All models estimated selectivity at ages 6-8 near 1 (Fig. 4 & Fig. 5). All models also estimated

Figure 3: Resulting spawning stock biomass (SSB, M t) estimates and CV (panels) among the candidate models and the 2022 accepted model 19.1a ("ADMB"). It is currently unclear why the CV is so much lower for the TMB models.

selectivity at age 2 to be near zero except for a period of about 2000-2010. For age 3, all models generally agreed and there appear to be meaningful annual changes, for example in 2008 selectivity was nearly 0.5, but dropped to around 0.2 by 2015.

Key differences among models are concentrated in ages 4 and 5. As noted previously, these are the two ages with poor residuals for the ParDev approach. The largest differences were starting in 2000, with the two nonparametric models estimated lower age-4 selectivity (Fig. 5). Age 5 selectivity was always estimated over 0.75 but again there are some differences annually. Overall, all three models estimated distinct patterns of age 4 and 5 selectivity. This is somewhat surprising given the similarity of the 2D and 3D AR(1) approaches. Differences in estimates in projected years are also meaningful, but described separately below.

Figure 4: Perspective plots of estimated fisheries selectivity for candidate models.

### Model selection and validation

OSA residuals for the Constant model show clear patterns and unexpectedly large OSA residuals (Fig. 6). This justifies more flexible selectivity forms. The ParDevs model shows much improvement, but still has lingering patterns in ages 4, 5, and 9, despite having a similar AIC value. The two non-parametric models eliminated the previous issues, and have no lingering age or year patterns. There does appear to be a lingering cohort pattern for the 2012 year class (diagonal positive residuals).

One important property of OSA residuals is that they are expected to have a standard normal distribution. Standard QQ plots (Fig. 7) show that the unexpectedly large residuals using the Constant model are eliminated by the three time-varying selectivity models. However, there still seem to be some distributional issues remaining, although we judge this to be of minor concern. We do note that the QQ plots for the two non-parametric models appear slightly better than the ParDevs approach currently used in 19.1a.

#### **Projection performance**

Fisheries selectivity for the current assessment year has no fisheries age composition data and so needs to be extrapolated by the assessment model. Further, reference point and ABC calculations rely on estimates of selectivity in the following year. These projected selectivities are expected to vary among models. The ParDevs model which has a random walk on parameters will have the same prediction as the last year with data, but increasing uncertainty with further extrapolation into the future (Fig. 8). The two AR(1) models

Figure 5: Annual estimates of selectivity at age (panels) with uncertainty (ribbons, +/-1 SE) for candidate models. The last year with fishery age composition is 2021 and denoted with a vertical line.

Figure 6: OSA residuals for the three candidate models compared to a model with time-invariant selectivity (Constant). Residuals are expected to have a standard normal distribution, so residuals larger than 3 are highlighted as a different shape.

Figure 7: Quantile-quantile plots of candidate models OSA residuals, which are expected to be standard normal and thus fall on the black line. Deviation from that implies model misfit.

will converge toward their stationary means, but the addition of the cohort effect for the 3D method will affect the estimates and transitory behavior toward the mean. For many ages there is little meaningful difference. The age with the most divergence among models is age 4, where selectivity is 0.91 for the ParDevs, 0.68 for the 2D-AR1 model, and 0.63 for the 3D-AR1 model. Interestingly the selectivity is increasing for the 2D model and decreasing for the 3D model for this age. We hypothesize this is caused by a cohort effect, although it is not strictly statistically significant.

Figure 8: Behavior of the selectivity modules when projecting past the last year with fishery age comp data (2021; vertical line). Annual estimates of selectivity at age (panels) with uncertainty (ribbons, +/- 1 SE) for candidate models. Ages 1, 6,7 and 8 are left off for visual clarity as they are nearly constant at 0 or 1 (see Fig. 5). The ParDev model is a random walk so its projections are constant with increasing uncertainty. The 2D-AR1 model reverts back to its stationary mean. The 3D-AR1 model accounts for cohort effects and thus behaves slightly differently from the 2D version.

There are thus important differences, especially in younger ages, for the predicted selectivity at the two important extrapolated years (Fig. 9).

#### **Retrospective performance**

Note, that the following results use the 2023 data. Overall, the 3D-AR1 model had the lowest retrospective bias in spawning stock biomass (Fig. 10 & Fig. 11 & Fig. 12). The 3D-AR1 model also consistently led to the lowest AIC across peels (Table3). When evaluating retrospective bias of age-specific selectivity, using the projected selectivity generally outperforms using the average selectivity from the 4 years prior to the terminal year of the assessment for models 1, 7, and 8 (Table 4). However, age-specific retrospective bias varied across selectivity functions. For example, projected selectivity from Model 8 had lower mean squared error for ages 2-4 than projected selectivity from Model 1, but much higher mean squared error for 9+ Fig. 13.

In terms of reference points, the 3D-AR1 model had the lowest retrospective bias and mean squared error for B0 and B40, but the highest retrospective bias and mean squared error for ABC and OFL (Table 4). Given that mean recruitment between 1978 and the the second to last year of the assessment is used to

Figure 9: Estimated selectivity with uncertainty (+/-1 SE) for the three models in the two important projection years.

Table 3: Delta AIC for retrospective model peels starting in 2023 (n = 7)

derive reference points. We also calculated Mohn's Rho for mean recruitment: Model 1 (ParDevs) = -0.0384, Model 7 (2D-AR1) = -0.0337, and Model 8 (3D-AR1) = -0.0287. In terms of projected vs average selectivity, projected selectivity had the lowest relative error (Mohn's Rho) across all models and the lowest mean squared error for models 7 (2D-AR1) and 8 (3D-AR1 cond). However, projected selectivity led to higher mean squared error in ABC and OFL for model 1 (ParDevs)(Table 5).

## Conclusions

Moving from ADMB to TMB has a few minor disadvantages which are clearly outweighed by the advantage of being able to estimate hierarchical models in a statistically defensible way. Hierarchical or "state space" models are now considered "best practices" for stock assessment (Punt 2023) and TMB is the best available tool to accommodate that framework. We were able to bridge from the ADMB model 19.1a to within a very small degree of error. This modeling framework will allow for important future extensions beyond fisheries selectivity as well (e.g., maturity and weight at age smoothing internally).

It is also clear that fisheries selectivity varies over time and that the current approach of random walk parameter deviations (ParDev model) is insufficiently flexible for some ages, as determined by residual patterns. The semi-parametric models explored here did not perform well, for reasons that are not completely clear at the moment. But two of the non-parametric models were very promising and had improved residual patterns, AIC, and retrospective performance. The 3D model had the lowest AIC and Mohn's Rho, with the 2D model about 10 units worse. We believe both non-parametric models would make for improved fits and projected selectivity for use in calculating management quantities. The major disadvantage of the non-parametric models is that they are about 10 times slower to fit than the parametric version with annual deviates (ParDevs), going from 4 to 40 minutes to optimize and do the delta method calculations. The non-parametric models also lead to increased retrospective bias in ABC and OFL, due to higher flexibility in selectivity for older age classes. This is trade off with reduced retrospective bias in SSB, R0, B0, and B40.

Estimating non-parametric components within an assessment takes care, as putting flexibility in the wrong component can lead to poor management advice (Szuwalski, Ianelli, and Punt 2018; Fisch et al. 2023). We feel confident that selectivity does vary through time, and that the forms examined here do a good job at capturing this change. The new forms also did not lead to major changes in status, trend, or reference points among different selectivity options, but there is a remaining discrepancy when compared to 19.1a that we need to investigate and resolve. Overall, we conclude that either non-parametric option would make for an improved model, with the 3D version fitting slightly better and having a cohort effect, but being more difficult to estimate.
